From the Medical Examiner's Point of View.—James Lock says the average medical director has an easy life and position compared to the life and position of the average medical examiner living in a town of average size, but not in the city or metropolis. Man for man, he believes that the medical examiners of this country are of the very highest character as a rule and that on the whole they render to the companies most valuable and reliable service. They must, or else how shall we account for the great savings in actual from expected mortality that has been the experience of life insurance companies for more than half a century? The medical practitioner in an almost or wholly rural community has surely a hard road to travel, and if now and then he makes a careless reply to a question on the examination blank he may deserve the sympathy rather than the criticism of his medical director. Perhaps he drove out the night before over muddy, almost impassable roads, to deliver a woman in a stubborn case, destitute perhaps of every necessity. He may receive a moderate fee for his work in a year or so, if his debtor succeeds in producing a good crop. Who shall estimate the hundreds of thousands of dollars contributed annually in such charitable work by the 8,000 medical practitioners who hold in this country commissions as medical examiners for life insurance companies? The great body of medical examiners is made up in greater measure of good men, ethical men of high professional character, who in larger environments would be today shining lights in their honorable profession. It has been more than interesting to watch the growth of the country practitioner; he ofttimes keeps himself more fully advised as to medical and surgical progress and attainment than his brother of the large cities. It is surprising to see what modern equipment is now found in a country practitioner's office; appliances up-to-date in every particular. With the medical directors manifesting confidence in their medical examiners; with the ranks of the latter filled with conscientious, well-equipped men, there will soon come to pass the entry of a golden era in the realm of medical examiners in the field.—*Lancet-Clinic,* June 21, 1913.

Plain Language from a Life Insurance President.—The following is a portion of a letter written by Mr. E. R. Roberts, president of the Amicable Life Insurance Company, to agents and examiners of that company. "There are numerous factors entering into the success of a life insurance company. The two principal ones being a large volume of new business and a scientific medical selection thereof. If the mortality should materially exceed the basis upon which the premiums are calculated, the company cannot escape failure. However scientific and well equipped the medical department of the home office of a company may be, it is equally necessary that the agents and examiners in the field faithfully and intelligently perform their duties in the selection of insurance risks. Any agent or examiner violating such sacred trust is a criminal and as such should be convicted by the courts and forever barred any future relation to the business of life insurance. . . . . We have certifications to certain tests by the examiner which were never made, also questions as to family history, etc., answered that were never asked the applicant by the examiner. We have taken up policies soon after issue on persons with Bright's disease, etc. These incompetent examinations are but the experience of other companies. This company will require, as soon as sufficient containers can be procured, a specimen of urine to be sent to the home office that microscopical tests may be made there in all cases regardless of the amount of insurance. It is due the good name of the many honorable and efficient agents and examiners that the inefficient and criminal ones be located and punished. This company will join other companies in a crusade to this end, and we expect the earnest assistance of reliable agents and examiners in ferreting out these criminals. We are having many of our policy-holders re-examined within the two-year limit by a traveling assistant medical director, and in some cases, re-examining all the work of certain examiners, and canceling policies where fraud is evident. . . . . There are certain towns in Texas in which there is not a single doctor acceptable to make examinations, therefore it is necessary for an agent to use only examiners authorized by this office, otherwise experience delays and also pay the fee of the unauthorized examination. This company has been compelled to install its own inspection department, and delays in the issue of policies hereafter will be caused by omissions and mistakes of agents and examiners. We have had great delays caused by the carelessness or incompetency of examiners in failing to properly fill out the examination blanks. Every question in each blank is important, or it would have been omitted and must be answered, or consequent delay. Examiners careless in omitting answers to questions are usually considered careless otherwise. . . ."—*Texas State Journal of Medicine.*

Book Reviews.

Medical Supervision in Schools. Being an Account of the Systems at Work in Great Britain, Canada, the United States, Germany, and Switzerland. By Edward Millar Steven, M.B., Ch. M. (Edinburgh), Royal Commissioner for South Australia, 1909. Price $2.00. London: Baillière, Tindall & Cox; Chicago: Chicago Medical Book Company.

It will be noted that the title of this book is the medical *supervision* of schools rather than the medical *inspection* of schools. This title indicates the modern attitude with reference to the health of school children, which attitude does not cease with the mere detection of physical defects, but aims to secure their correction. Having been appointed by the Government of South Australia to inquire into the subject of medical supervision of schools in Great Britain, Canada, the United States, Germany, and Switzerland, the author was able to collect a set of data of unusual value and interest. The London system which has already reached a high degree of elaboration is described in detail. Of particular interest is the fact that the parent is requested to be present at least at the first examination of the child by the school physician. The various notification forms which enable the authorities to follow up the cases, and finally to prosecute neglectful parents or guardians are strikingly elaborate in their variety and are undoubtedly effective. The open air schools and the special schools for the mentally defective, the physically defective, the deaf and the blind are described with the aid of a number of excellent photographs. The Bradford system is justly regarded by the author as the most perfected system of medical inspection found anywhere. Initiated by Dr. Kerr and maintained by a zealous school board, this system, with its school clinics, notifications of parents, disinfection of homes, open air schools, etc., is one that may well be imitated in other parts of the world. Glasgow has a special school for semi-deaf cases. In describing medical inspection in New York the author begins with the humorously inaccurate statement that "the City of New York, which is divided into five boroughs, is under the control of a lady, Dr. Josephine Baker, who holds the position of chief medical officer for the Education Department." The valid criticism is made, and it would be well if the Health Department of New York would take notice, "that treatment of children by nurses, if universally adopted, cannot be too strongly deprecated." Possibly the author is somewhat too "personal" when he states that "one glaring anomaly noticeable to a Britisher is the lack of care exercised by the average American general practitioner in regard to his personal appearance." One of the striking features of medical supervision in Germany is the general introduction of school baths. The discipline in the schools is regarded as almost perfect. There can be no doubt that in this book the author has gathered a mass of information of value to all those who are interested in the welfare of children, and particularly to educational and public health authorities.

Epidemic Cerebrospinal Meningitis. By Abraham Sophian, M.D., formerly with New York Research Laboratory. Twenty-three Illustrations. Price $3.00. St. Louis: C. V. Mosley Company, 1913.

New York and the country in general need no introduction to the author of this book whose work during the extensive epidemic of meningitis that ravaged the Southwest during 1912 received such grateful recognition. The present volume which represents the first monograph on meningitis in the English language is the fruit of the author's extensive laboratory and clinical experience. It deals with every phase of meningitis, from a historical review to the technique of the administering the specific curative serum. In addition the author describes his own contributions to the various theoretical and practical phases of the subject. One of the most important of these deals with the method of introducing the antitoxic serum as guided by blood pressure observations. Thus while there is usually a fall of blood pressure following lumbar puncture, there is a further drop on injecting the serum. If a small quantity of serum is injected slowly there is apt to be a smaller drop in the blood pressure than when a large quantity is allowed to flow in rapidly. Using the gravity method of introducing the serum one can accurately control the speed with which the latter is allowed to enter the subarachnoid space. The application of this method during the Texas epidemic caused a considerable reduction in mortality. The author also describes his studies on protective inoculation with vaccines made from killed meningococci, a subject that offers considerable promise. A collective study of the Texas epidemic of 2,280 cases showed a mortality under serum treatment of 37 per cent. as against a mortality of 77 per cent. in cases that were not treated with serum. The author is to be congratulated on his excellent summary of the present knowledge of meningitis and on his own important pioneer studies.

Surgery. Its Principles and Practice. By Various Authors. Edited by William Williams Keen, M.D., LL.D., Emeritus Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Volume VI. With 519 illustrations, 22 of them in colors. Price $7.00. Philadelphia and London: W. B. Saunders Company, 1913.

In dealing with the present volume the reviewer finds himself in something of a quandary; for it is quite hopeless to attempt to do justice to it in the space available. Even a simple enumeration of the titles of the articles contributed by the more than sixty authors is out of the question, while to single out a few for special mention is to be by implication unjust to most of the others. The five volumes of the system originally planned were completed in 1909, but even in the short time that has elapsed since the appearance of the first one sufficient new material of importance has accumulated to make it desirable to summarize the advances made in surgery by the preparation of this supplementary volume. Accordingly, most of the original authors have contributed articles in which the discussions of the subjects dealt with are brought fully to date, while a number of new sections, such as those on the use of salvarsan in syphilis, the treatment of cancer by desiccation and fulguration, the experimental work on cancer with eosin and selenium, etc., have been added. A chapter of particular interest is the one in which Crile deals with surgical shock, and another is his discussion of the allied subject of anociassociation. New material of much importance has been contributed on methods of operating on the thorax under increased or diminished pressure, on anesthesia by improved methods, on the use of iodine for sterilizing the skin, on the surgery of the hypophysis, etc. A feature that will add greatly to the convenience of readers is the general index covering all six volumes.

Textbook of General Pathology. By the following contributors: A. P. Beddard, London; A. E. Boycott, Manchester; C. H. Browning, Glasgow; A. E. Garrod, London; J. S. Haldane, Oxford; I. Walker Hall, Bristol; A. F. Hertz, London; F. W. Mott, London; M. S. Pembrey, London; J. Ritchie, Edinburgh; J. H. Ryffel, London; S. V. Sewell, Melbourne; J. Lorrain Smith, Edinburgh; E. Ainley Walker, Oxford. Edited by M. S. Pembrey and J. Ritchie. Price $5.00 net. New York: Longmans, Green & Company, 1913.

There have been many excellent textbooks on general pathology, but in almost all the author has devoted most of his space to a discussion of the particular subject to which he has made contributions, and has somewhat slighted other phases in which he was less interested. In order to meet the difficult problem of the production of a book in which each phase of general pathology is adequately treated, it is necessary to give each section to some one who has made a specialty of the subject. Because this plan has been followed the text under consideration is excellent; the various chapters have been assigned to men who have interested themselves in the special subject upon which they have written. Thus, the pathology of the blood is covered by Boycott, immunity by Browning, tumors by Ritchie, the circulation by Boycott, the nervous system by Mott, respiration by Haldane, anomalies of metabolism by Garrod, gout by Walker Hall, etc. Each section is thoroughly modern and shows the result of original work by the writer. The editing has been careful, and there is little overlapping of subjects. The chapter on the nervous system is the only one which contains any number of illustrations, the nature of the other chapters requiring only a few charts and diagrams to explain the text satisfactorily. In the chapter on digestion some of the diagrams drawn from *x*-ray plates furnish interesting illustrations of the muscular activity of the stomach and intestine in various pathological conditions. The bibliography has been kept within reasonable limits, only important articles and textbooks being mentioned. The work is an excellent compilation for the student, and the practitioner will find much to interest and instruct him, for throughout the practical viewpoint has been maintained, and the application of recent experimental work to medicine kept fully in mind.

Technique microscopique, d'après Böhm et Oppel par Etienne de Rouville, Doctor des sciences, charge d'un cours complémentaire à l'université de Montpellier. Cinquième édition, revue et considérablement augmentée. Avec 17 figures dans le texte. Price 8 francs. Paris: Vigot Frères, 1913.

This fifth edition of Microscopic Technique which has been adapted from the well known text of Böhm and Oppel by the French editor, is an extremely useful volume for the practical laboratory worker. It combines many of the advantages of the German original with a fairly complete presentation of those technical methods which have been more particularly developed by the French themselves. Among the new features which have been introduced into this edition are a description of the methods of dark field illumination, the more recent methods for staining special elements of the blood, and the new procedures for the demonstration of mitochondria. An excellent bibliography is appended.

Technique Clinique Médicale et Semeiologie. By Dr. Sergent, Doctor of Hospitals. Paris: A. Maloine, 1913.

So many internes follow their chiefs about the wards hearing remarks here and there about methods of infection in typhoid, the theories of diabetes, hemolysis in jaundice, etc., etc., but go out without learning the practical clinical work. They do not know how to apply their book knowledge. The first requirement is technique of examination; the second is teaching of the significance of symptoms. The book of 700 pages is intended to join the practical and theoretical principles to enable clinical study. It covers the examination of respiratory and circulating systems, abdominal organs, urinary organs and nervous system, including also laboratory examinations. It is an excellent clinical guide and is filled with numerous illustrations, charts, *x*-ray plates, etc. It is clear and concise and will be of use to practitioners as well as students.

The Modern Treatment of Nervous and Mental Diseases. By American and British Authors. Edited by William A. White, M.D., Superintendent of the Government Hospital for the Insane, Washington, D. C.; Professor of Nervous and Mental Diseases in the Georgetown University; Professor of Nervous and Mental Diseases in the George Washington University; Lecturer on Mental Diseases in the U. S. Army and U. S. Navy Medical School, Washington, D. C.; and Smith Ely Jelliffe, A.M., M.D., Ph.D., Adjunct Professor of Diseases of the Mind and Nervous System in the Post-Graduate Medical School and Hospital; Visiting Neurologist to the City Hospital; Consulting Neurologist to the Manhattan State Hospital, New York, N. Y. Volume I. Illustrated. Price $6.00 net. Philadelphia and New York: Lea & Febiger, 1913.

The editors' statement in the preface of this work outlines the scope of the undertaking which "lays emphasis upon the psychical side of life as being worth quite as much consideration as the physical. It sets forth doctrines of nervous and mental hygiene, reconstructive factors in social organization as applied to human ills, and endeavors to present a broad front to the pessimistic nihilism in therapeutics that has been too long current in these fields, because the doctor's eyes have been too closely focused on the individual examples and results of human accidents." One perceives throughout the work a recognition of its newer teachings of biology and of the psychological basis of insanity. A brief summary of the contents of the first volume may suffice to indicate the scope of its subject matter. William A. White writes on eugenics and heredity in nervous and mental diseases. The fact is emphasized that eugenics is not concerned solely with developing a race of physically perfect people, but aims to develop a race in which character figures as a desirable quality. S. S. Colvin discusses education as a modification of behavior for social adaptation. Education is conceived as a means of developing personality, which consists of a stock of useful habits and of vital ideals that constitute the ends of rational volition. Sexual problems in their nervous and mental relations are described with the unusual combination of clearness and delicacy so characteristic of the pen of Havelock Ellis. The educational treatment of the feeble-minded, a subject that has attracted so much attention within recent years, is discussed by Henry H. Goddard. William Healy, Director of the Juvenile Psychopathic Institute of Chicago, has written the chapter on delinquency and crime in relation to mental defect or disorder. The subject of immigration and the mixture of the races in relation to the mental health of the nation is dealt with in a comprehensive and sympathetic manner by Thomas W. Salmon. The plea is made that efficiency and humanity should have equal place in the enforcement of our immigration laws; there should be greater care for the safety of helpless insane immigrants. H. W. Mitchell details the treatment of alcoholism and the alcoholic psychoses. The treatment of the nervous and psychoneuroses is discussed by Ernest Jones, with a full appreciation of the methods of the Freudian psychoanalytical school. John Jenks Thomas writes on the traumatic neuroses and psychoses and the occupation neuroses, and Henry A. Cotton presents a most illuminating chapter on the disturbances of the internal secretions and of the sympathetic system. E. E. Southard discusses mental diseases of somatic but extranervous origin, the so-called symptomatic psychoses. The manic-depressive psychoses and their treatment are dealt with by Clarence B. Farrar, and the treatment of dementia præcox and allied conditions is discussed by C. Macfie Campbell. A most interesting chapter is that by Adolf Meyer on the treatment of paranoic and paranoid states. The possibility of cure in these conditions is fully discussed and illustrated with case reports. Bernard Glueck writes on the prison psychoses; and Albert Moore Barrett, on presenile, arteriosclerotic and senile disorders of the brain and cord. The application of legal measures in their remedial bearings constitutes a most useful chapter under the authorship of Frederick A. Fleming. The military relations of nervous and mental disorders are discussed by R. L. Richards, and the functions of the hospital in nervous and mental disorders are clearly described by James V. May. Full and up-to-date bibliographies are appended to each of the chapters.

Die Behandlung der Krankheiten der Behaarten Kopfhaut. By K. Herxheimer and K. Altmann, Frankfurt a. M. Price 1.50 marks. Halle A. S.; Carl Marhold, 1912.

From eczema to tumors the diseases are cursorily taken up in this little book and some good ideas on treatment are given.

The Posture of School Children. With Its Home Hygiene and New Efficiency Methods for School Training. By Jessie H. Bancroft, Assistant Director Physical Training, Public Schools, New York City; ex-Secretary American Physical Education Association; Member American Association for the Advancement of Science; Author of "School Gymnastics," "Games for the Playground, Home, School, and Gymnasium," etc. Price $1.50 net. New York: The Macmillan Company, 1913.

The growing interest in the physical welfare of school children is mirrored in the many valuable studies that have been made within recent years, dealing with various aspects of school life as related to the physical defects of the child. That the posture of school children should be made the subject of exhaustive discussion in a single volume, is quite natural, in view of the many points at which posture touches the physical, mental, esthetic, and economic needs of the individual of today. Correct posture is indeed one of the criteria upon which is based the judgment of a child's fitness for graduation from public school in New York City. The author brings to bear upon her handling of this topic the fruits of wide experience and the inspiration of rare enthusiasm. She discusses the general significance of erect carriage in the individual and the race; the methods of judging correct and incorrect posture, particularly with the aid of the now well known vertical line or "window pole" test; the mechanical difficulties of the erect position; the various deformities of the spine; the head, chest, shoulders, pelvis, abdomen, and feet; posture in adults; erect posture in sitting, standing, walking, and stair climbing; the methods of correcting poor posture; home exercises; dress; training the muscular sense; and erect posture as an educational aim and as an expression of intelligence and character. One of the most important contributions which the author has made to this subject has been the introduction of efficiency methods in judging and maintaining correct posture—in other words, the standardization of correct posture. A triple test has been devised whereby the teacher can grade a pupil with respect to this quality. This test consists in observing the pupil while he is standing, while he is walking, and while he is at exercise. The illustrations in this book are particularly numerous and helpful, and the full page photographs of portraits and statues from art galleries add an attractive and esthetic tone to the book. The author is to be commended for having written a volume of immeasurable value from scientific, educational and medical viewpoints.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-fifth Annual Meting, Held in Washington, May 5, 6 and 7, 1913.

THE PRESIDENT, DR. GEORGE A. LELAND OF BOSTON, IN THE CHAIR.

(*Concluded from page 506.*)

Second Day—Tuesday, May 6.

Election of Officers.— *President*, DR. THOMAS HUBBARD of Toledo, Ohio; *First Vice-President*, DR. FREDERICK E. HOPKINS of Springfield, Mass.; *Second Vice-President*, DR. GEORGE E. SHAMBAUGH of Chicago, Ill.; *Secretary*, DR. HARMON SMITH of New York City; *Treasurer*, DR. J. PAYSON CLARK of Boston, Mass.; *Librarian*, DR. JOSEPH H. BRYAN of Washington, D. C.; *Member of Council*, DR. GEORGE A. LELAND of Boston, Mass.

Phlegmons of the Upper Respiratory Tract: Report of a Case.—DR. F. E. HOPKINS of Springfield, Mass., read this paper. He said that the principal point which the report of his case illustrated was the possibility of erosion of large blood vessels. He saw the patient on May 23, 1910. He was a male, twenty-six years of age, of poor resistance because of having led an irregular life and having had a recent acute illness. He had suffered from measles early in the month and while convalescing had taken cold, the particular manifestation being a sore throat. There was a marked swelling on the left side, with severe pain, but he was not prostrated, being at this time dressed and about the house. His pulse was 80 and temperature 100° F. During most of his illness the pulse rose only to 80 or 90 and the temperature at no time exceeded 101° F. No fluctuation could be made out. The following day there was no evidence of pointing, and fluctuation could not be felt. Deep incisions were made, but these yielded no pus and little bleeding took place. Two days later a hemorrhage occurred which was controlled by pressure. On the 27th a terrific hemorrhage occurred and quickly proved fatal. A post-mortem was not allowed, but such examination as could be made immediately following death showed rupture through the posterior pillar, the flood from the eroded carotid finding exit here. He believed that such a mass of cellular infiltration should be explored by a blunt instrument, even the finger, following unfruitful incision. In this case the patient objected vigorously, as did the parents; and as a peritonsillar abscess usually soon ruptured into the incision or burrowed its way to the surface, further interference was not insisted upon. As to the cause of peritonsillar infections they readily accepted the bacteriologist's dictum that the throat at all times harbored bacteria ready marshaled for invasion, and since the crypts of lymphoid tissue were portals easily assailed, infections of this region should be frequent and systemic involvement severe. The wonder was, not that phlegmons threatening life occasionally developed, but rather that such serious invasions were so rare and an active professional life might pass and not a single case come under observation. Microscopical findings were of little value in determining the treatment of these cases. The stage of progress decided that early and effective drainage was the best assurance of a favorable prognosis. Suffocation from flooding the larynx by the sudden rupture of an abscess had been reported, and tracheotomy had been required because of closure of the pharynx by infiltration and edema, but the complication he wished to emphasize was that of erosion of blood vessels by the necrotic process.

Inflammation of the Lateral Columns of the Pharynx Leading to Abscess Formation, with Report of Cases.—DR. HENRY L. SWAIN of New Haven, Conn., said that any isolated mass of lymphoid tissue could in a general way be expected to act, when inflamed, exactly after the fashion of the faucial tonsil and could have, like the latter, simple acute, follicular, rheumatic, diphtheritic, and phlegmonous inflammations. As knowledge became more widespread concerning what happened to the adenoid or pharyngeal tonsil, they learned to know, as years went by, that it might have acute as well as chronic inflammation. The same was true of the lingual tonsil. In recent years much had been written in the journals concerning inflammation of the lateral columns of the pharynx, and he had a presentiment that if they continued to remove, root and branch, from their young children all of their adenoids and faucial tonsils, there would be abundant need for them to devote increasingly more and more attention to these masses of lymphoid tissue as well as to the lingual tonsil. Hundreds of observations existed to attest to the fact that when, in years gone by, adenoids were removed in young children and the faucial tonsils were left untouched, the latter subsequently enlarged into a perfectly healthy growth as though needed by the system, and as though trying to supply something to satisfy this lack or want. If the faucials were thus also ruthlessly removed, just as surely as the sun rose and set there would be enlargement of the lingual tonsil or lateral columns of the pharynx chronicled, as there had been of the faucials following the older simple adenoid operation. And if this was logical and true, they should find not only acute inflammation of these structures, but also the phlegmonous. They had assumed more or less arbitrarily that, as the lateral column of the pharynx was no mean mass of lymphoid tissue, and as it had been known to have all of the other kinds of inflammation to which lymphoid tissue was heir, they had a logical right to expect that there might be also the phlegmonous type, and Dr. Swain proposed to submit the facts concerning certain cases to prove that such might be the case. Recently he had had six cases of edema of the larynx. In two there was no quinsy at all. There was inflammation of the lateral column of the cord in both these instances, and there was in one a marked general, what might be called a rehumatic, infection, where various joints of the body were swollen and inflamed, with rapid jumps from these to other joints, and with no persistence of the symptoms in any one place for any length of time. In these various cases of edema one had to look to some other cause than pressure.

Phlegmons of the Upper Respiratory Tract.—DR. JOHN O. ROE of Rochester, N. Y., said that phlegmon was simply another name for inflammation, although clinically it was regarded as of an extraordinarily intense inflammation and looked upon as being of a more or less malignant character. Thus they might have an inflammation of this character in any part of the body, the intensity of which was dependent upon the virulence of the infection and the resistance or the lack of resistance of the patient, or of the tissues, to such infection. Owing to the frequency with which such inflammation caused difficult breathing or choking, when involving the upper air passages, it had received the name of angina, which signified strangling, and which was commonly applied to any inflammatory affection of the throat or fauces that might interfere with normal breathing. Inflammations of a severe grade termed phlegmon might involve any or every portion of the upper respiratory tract. They almost invariably found a phlegmon attacking those whose general condition had become generally weakened and whose defenses had been broken down by some diseased condition or dyscrasia. Dr. Roe reported several cases more or less in detail. He said that the treatment of these infections and virulent inflammations required no special law unto itself, and must be dealt with according to its location and associated complications.

Report of a Case of Phlegmon Starting as a Peritonsillar Abscess and Extending Downward as Far as the Second Ring of the Trachea.—DR. GEORGE L. RICHARDS of Fall River, Mass., reported a case as an example of a severe pharyngeal phlegmon, having its origin primarily in a peritonsillar abscess, and secondarily in a diseased tonsil.

Phlegmons of the Upper Respiratory Tract.—Professor FERD. MASSEI of Naples, Italy, read this paper by title. He was unable to be present because of illness.

Dr. HENRY L. WAGNER of San Francisco, Cal., said there were so many conditions that produced these phlegmons that sooner or later they would see a change in the classification of such cases. They all knew that a streptococcus infection did not always produce conditions of this kind. It was very important that they should recognize systemic infections. They might either examine the urine or make use of reports. He thought that all cases were the result of systemic disturbances. He had met with a peculiar case of a descending inflammation produced by the pneumococcus. It began in the eye. The oculist had sent the patient to him when the infection had traveled downward. The etiology of the edema had been spoken of by Dr. Swain and was caused by some condition existing in the blood vessels. Often edema of the nasal cavities followed in cases of anaphylaxis.

Dr. WILLIAM E. CASSELBERRY of Chicago said that the impression abroad was that these phlegmons were synonymous with erysipelas, especially of the skin, which later affected the mucous membrane and produced an extra severe inflammation. Inflammation of the skin caused by erysipelas subsequently caused phlegmonous inflammation of the throat which made it plain that the two were one

and the same thing. He related the case of a patient who had a condition that was suggestive of peritonsillar abscess. After a time the condition subsided and she complained that there was something the matter with her ear. An examination showed a weeping edematous condition. The following day she developed erysipelas of the auricle which later extended over the entire face and part of the body. She made a complete recovery. He had met with four cases of phlegmon in the throat, two with Ludwig's angina and two with peritonsillar abscesses. They were conscious for a period of from four to six hours; then developed edema of the lungs and died.

Dr. D. Crosby Greene of Boston believed that in many cases where the inflammation was limited to one side of the throat, the edema of one side of the larynx being definitely marked with external swelling of that side, median incision was the method of choice for obtaining drainage. He related a case in which he had followed this procedure, the operation being done under local anesthesia and being followed by almost immediate relief from pain and dyspnea. One advantage of this incision was that the exposure of the trachea at the lower end of the wound made instant tracheotomy, if necessary, a very simple procedure. This patient recovered rapidly from his local infection, but developed a streptococcic pneumonia from which he also recovered. He had known of several other cases which had been incised and drained successfully by this median incision. This was a resource which should be borne in mind.

Dr. Cornelius G. Coakley of New York said that the cases related represented two classes clinically. In one, if they could get a good light, they would see a definite area of fluctuation which could be opened through the mouth, but this was not the class of cases that required their serious consideration. The cases which he had found to terminate fatally so frequently were those with a moderate or slight tonsillitis. They complained of sore throat and nothing could be seen alongside the throat. Sometimes they found nothing and then at the end of twenty-four hours a hard swelling would be noted, with beginning edema on the side of the wall of the pharynx, and within another twenty-four hours the patient would die of suffocation. If tracheotomy had been performed the patient might have died of septic pneumonia. If an internal cut was made they often failed to find pus. Dr. Coakley said he had tried the internal operation, but felt that the only way to relieve these patients was by an external operation. The incision was made along the sternocleidomastoid muscle. In two cases that had ended fatally he had found little blood and serum. This was a serious type of cases and an external incision made early was the correct procedure.

Dr. James E. Logan of Kansas City, Mo., said he believed the classification made by Dr. Coakley was a very important one. In many of these cases it was very difficult to find a distinct fluctuation or any evidence of pus. He had seen a very interesting case in February. The patient had had a slight tonsillitis, from which he recovered. Three or four days later he was taken suddenly ill with edema; there was an edematous swelling on the left arytenoid cartilage. He first gave these patients a purgative and then made cold applications for sixty hours. At the end of this time the edematous condition would entirely disappear. In this patient to whom he had referred he believed that the condition was due to the alimentary canal, as the patient acknowledged having partaken of a hearty dinner the night before. There was also a close relationship with angioneurotic edema. He was opposed to scarification in these instances and thought the application of ice resulted in great benefit.

Dr. Robert C. Myles of New York said that this subject had had his serious consideration during the past few years for he had had some very desperate cases with which to deal in his practice. He had seen only one death from a phlegmon of the upper respiratory tract. He believed that recovery in such cases had been due to surgical interference probably aided by injections of antitoxins. They used icebags over the part. He had often wished that some one would report on the autopsies in these cases. He was often puzzled as to where to cut, as in certain phlegmons there would be but a small foci of pus and yet the condition would be most serious. So far as the edema was concerned Dr. Myles said he believed that it was due to the physical laws of osmosis. In one case the swelling was so great that it went above the hyoid. He entered the tube-like fossa, two inches long, and in five minutes the patient obtained complete relief. The condition was due to pressure upon the superior thyroid vein, either direct or indirect. Another incision was made low down and a string placed in. The wound healed and the patient had been well since. He would advocate the external operation when other means failed to give relief.

Dr. John R. Winslow of Baltimore, Md., said that a year ago he had seen a case similar to the one that Dr. Richards had reported. This case occurred in a colored man, who had been suffering from an attack of tonsillitis, and this was probably followed by peritonsillar abscess. When he appeared at the clinic six weeks later he complained of soreness of the side of the neck and difficulty in swallowing, but there was no dyspnea. There was a marked edema of the perilaryngeal tissues on the left side of the epiglottis, but no swelling or obstruction inside of the larynx. A fine thread of pus trickled over the left side of the epiglottis, the source of which could not be determined. During the night under the hot applications which were ordered the abscess burst and the patient disappeared from observation for six weeks. He then returned and gave a history of five or six successive abscesses which had broken. He was in such a bad condition that it was decided to do a tracheotomy. An hour and a half before the time appointed for the operation a telephone message was received that the patient was dying. He hurried to the hospital and did an emergency operation under local anesthesia. The minute he incised the soft tissue a large volume of pus rushed forth. The tracheal walls were enormously thickened. After opening the trachea the patient collapsed and was apparently dead. He revived under the use of oxygen and amyl nitrite, and eventually recovered from this, but he had never been able to do without his tracheal tube. The larynx seemed to be in a condition of extreme collapse and there was paralysis of all the laryngeal muscles. He believed that this was a neglected case of quinsy, with gravitation downward in the tissues of the neck, and the development of perilaryngeal and peritracheal phlegmon.

Dr. Grenfield Sluder of St. Louis, Mo., said that it seemed to him that there was one feature that had not been clearly brought out in the papers, and that was the seriousness of peritonsillar or phlegmonous sore throat. The cases reported by Dr. Casselberry proved the identity of these sore throats with erysipelas, and he would like to add his testimony to this effect. He cited a case in which a violent sore throat with a high grade edema of the soft palate developed into erysipelas and extended over the body and resulted fatally on the second day. There was a streptococcus infection behind without admixture apparently.

Dr. Emil Mayer of New York said he would like to know about the patients who recovered with the tracheal tube in position. He had had cases where tracheotomy had to be performed in a hurry; one patient was found to be choked up when the tube was removed, and it had to be replaced in a hurry; this was necessitated because of an infolding of the epiglottis. He removed the epiglottis in a case where this occurred and the patient had been perfectly well since.

Dr. Henry L. Swain of New Haven, Conn., referred to a case occurring in his own town which was similar to the one Dr. Richards had reported. The patient was a physician. The abscess pointed toward the middle of the neck at the sternal end of the clavicle on one side, and subsequently on the other. There was such a marked stiffness of the neck that it was nearly a year before the patient could raise his chin into proper position. With regard to the external incision in Ludwig's angina he had mentioned in his paper a case in which it became necessary to do a tracheotomy where there was employed an instrument, similar to that of Dr. J. Solis Cohen for bloodless tracheotomy, which was a very convenient thing. The patient died a few days later from sudden and profuse hemorrhage, and practically drowned in his own blood. They did not pay enough attention to such a thing as the possibility of abscess of the lingual tonsil when dealing with these cases of phlegmon extending down the neck.

Dr. John O. Roe of Rochester, N. Y., said that as to the term phlegmon, any inflammation of the upper air passages, whether due to erysipelas, scarlet fever, measles, or what not, was a phlegmon. This was a term that was used loosely. With regard to the constitutional conditions that had been touched upon by Dr. Logan and Dr. Myles, and the use of ice in local treatment, this was all of great importance. One seemed to lose something in adopting surgical measures and losing sight of the constitution of the patient. In many of the cases reported the local condition was no doubt preceded by some septic condition. One should begin to treat the constitutional condition at the same time that one treated the local condition.

Dr. George L. Richards of Fall River, Mass., said that he had had one death occurring from edema of the larynx. In this case he made an incision and the difficult breathing was relieved. The patient was then left in charge of the family physician, and he was told that she had simply stopped breathing. He thought that probably he should have done a tracheotomy in this instance. In many cases he placed the head lower than the feet.

The Seat of Latent Diphtheria in the Upper Air Passages.—Dr. Henry L. Wagner of San Francisco, Cal., read this paper.

Third Day—Wednesday, May 7.

Primary Carcinoma of the Epiglottis, with Report of a Case.—Dr. Emil Mayer of New York read this paper. He said that primary cancer of the epiglottis was a rare disease, and up to the present time the treatment had consisted of surgical intervention or the use of radium and the *x*-ray. Dr. Mayer had seen two cases of cancer of the epiglottis. The first case was diagnosed of probable malignant disease of the epiglottis, and the subsequent history was that of primary epithelioma of the larynx with subsequent metastasis, laryngectomy, and death. The second case was reported as follows: The patient was a male, sixty-four years old, who consulted him on June 9, 1912. He complained of some slight pain in swallowing for the past six weeks, especially after the swallowing of cold liquids. His general condition was good. He said he would not have paid any attention to his symptoms had it not been for the fact that both his father and mother died at the same age as the patient was at present. A sister and a brother had died of phthisis and two brothers of diabetes. An examination showed some edema of the uvula and numerous small white spots upon the tongue and inner surface of the cheek. His condition was diagnosed as leukoplagia buccalis. He gave no antecedent history of lues. His condition improved under treatment and in the following month he went abroad. On January 10, 1913, he again saw him, and he reported that the improvement after the previous treatment had not lasted very long and that he had some discomfort after swallowing cold liquids. Dr. Mayer found that the uvula was normal in appearance and there was present a nasopharyngeal catarrh and the white patches were still present. There were no other evidences of any diseased condition of the throat. About three weeks later he found a new condition on the laryngeal surface of the epiglottis. In its center there was a deep ulceration surrounded by a thickened mass. He promptly removed a portion of this, and Dr. Mandlebaum sent back the diagnosis—cylindrical cell carcinoma. They had before them a case of carcinoma of the epiglottis in its very earliest stages, as the breaking down and induration had all appeared within a fortnight's time. In order to be quite sure that this was the original site of the cancerous disease, the patient was admitted to Mt. Sinai Hospial and subjected to a very thorough examination. As a matter of routine blood tests were made, and here they received the first notification that the Wassermann reaction was strongly positive, although the patient gave no history of lues. On February 20th the patient was anesthetized and the suspension laryngoscope was placed in position without, however, including the epiglottis. The epiglottis was then seized and with a long-handled knife amputated, cutting from right to left and then from left to right. There was very little bleeding at the time of operation. Twenty-six hours after the operation the patient began to expectorate large quantities of blood; this was checked by sprays of peroxide of hydrogen, ice internally and externally. Within a short time the patient was able to swallow soft foods at once, liquids later, and in ten days from the time of operation he left the hospital. From the foregoing it would be noted that the writer was enabled to see the very beginning and note the development of carcinoma of the epiglottis. An early operation was permitted and the organ removed entire through normal tissues. This was the first operation of its kind ever performed under the ingenious suspension laryngoscope of Killian, and it was earnestly hoped that there would be neither recurrence nor metastases.

Dr. J. Gordon Wilson of Chicago, Ill., said that Dr. Mayer was to be congratulated on getting the case so early and so preventing metastases. He was interested in the epiglottis. Was this a useless organ? He had found that removal of the epiglottis did not interfere with swallowing. When the epiglottis was examined in an adult they found the posterior part covered with taste bulbs. Another function given the epiglottis was that of closing the opening to protect the larynx from the food during the process of swallowing. This function was not so important in the adult as in the child.

Dr. Lorenzo B. Lockard of Denver, Col., said that he was interested in the method used by Dr. Mayer. He had operated upon several cases, using the electric snare, the cold snare and other methods, but he had not been able to remove half as much as Dr. Mayer in the mouth. In ordinary conditions the complete removal of the epiglottis was not necessary. He had never been able to see that the removal of the epiglottis affected deglutition. He had removed it about one hundred and fifty times and found no difficulty except where there was a destruction of the larynx. When the disease involved other parts as the arytenoids and bands the removal of the epiglottis would be followed by regurgitation of food which as time went on became better.

Dr. Arthur Watson of Philadelphia, Pa., believed that the epiglottis acted as a gutter to divert the mucus that dropped from the palate onto the base of the tongue, and the saliva that flowed over the base of the tongue, to the sides of the pharynx, thus guiding it around the entrance of the larynx. He thought he had observed the result of the absence of this function in cases of extensive destruction of the epiglottis, manifested by sudden attacks of choking.

Dr. William L. Ballenger of Chicago said that some time ago he removed the epiglottis and the patient had difficulty in swallowing for two or three weeks, but this was not due to the absence of the epiglottis. The wound did not close by primary intention as expected. This epiglottis was removed deeply at the base. The difficulty in swallowing was probably due to the external wound.

Dr. Emil Mayer of New York, inclosing the discussion, said the recurrences of cancer after the removal of the epiglottis was usually slow. In one case there was no recurrence until after nine years. This was an epithelioma of the epiglottis removed with the suspension apparatus. The operation could be done more surgically and one need not cut into the malignant growth at all. The incision was made through normal tissues. Whatever function the epiglottis might have it seemed that the patient could get along without it. Dr. Mayer considered the suspension instrument of Killian as a great advance in their work.

The Significance of Plasma Cells in the Tonsil.—Dr. J. Gordon Wilson of Chicago made this preliminary report and demonstrated the plasma cells in tonsillar and adenoid tissues.

Dr. Algernon Coolidge of Boston said that he had recently studied the question of the normal size of tonsils in children and found that while the tonsils varied very much in size in adults, in children they varied surprisingly little. In a series of 200 tonsillectomies in children those tonsils which had previously been diagnosed as enlarged or hypertrophied by different physicians weighed on the average less than those which had been called small, but were removed for constitutional reasons. The apparent difference in size was often due to the varying relation of the tonsil with the soft palate. In a child of seven it was very unusual to find a tonsil of less than thirty or more than fifty grains.

Dr. Henry L. Swain of New Haven, Conn., said that the Association was to be congratulated in having presented to it such an excellent paper. Work of this kind should stimulate them to further inquiry into the physiology of the tonsil and to estimate what its actual function was. He was not clear in his mind as to the nature and function of these plasma cells and welcomed any further elucidation.

Dr. Henry L. Wagner of San Francisco, Cal., said that if one considered the cells of the nose and the mechanical conditions he would find that the germs in the nose were attacked by the cilia on the mucous membrane. During normal activities the cells would put up a defense against the organism; if the cells were impaired then their activity was lessened and the mucous membrane became a source of infection. Gland activity after eating or secreting should be considered. After certain activities the plasma cells would be found reacting both physiologically and otherwise.

Dr. George B. Wood of Philadelphia, Pa., said he had noticed an almost constant occurrence of plasma cells in the tonsils. It was generally accepted to-day that the presence of plasma cells indicated a condition of sub-acute inflammation. He had noticed especially in connection with his studies of tuberculosis that though the tonsil was quite readily invaded by the bacteria there was a distinct resistance of the tonsil parenchyma to the action of the bacterial toxines, for instance, an infection of the tonsillar tissues with tubercle bacilli rarely produced progressive lesions; more frequently it was found in a latent type with a tendency toward fibrosis of the tubercles. Should these bacilli infecting the tonsil gain access to the efferent

lymphatics and invade the regionary lymph nodes, there followed a rapid destruction of the lymph nodes out of proportion to the progress of the disease in the tonsil. This had been demonstrated experimentally and confirmed by clinical observation. The presence of plasma cells indicating a mild degree of inflammatory reaction was evidence that the tonsil was being subjected to frequent insults from bacterial invasion, and that they had reacted with the production of a localized immunity.

Nitrous Oxide Gas, Essence of Orange, Ether, and Sequestration in General Anesthesia for Operation in the Upright Position.—Dr. Thomas R. French of Brooklyn read this paper. He also demonstrated the latest model of chair-table. He said that they were now able to state, as a result of the movements of the new operating table and also as a result of the tests made in their clinic in the Long Island Hospital, of various methods of general anesthesia, that operative work in the upright position could be done with still less loss of blood, with the need of still less of the anesthetic, and with less disagreeable conditions during recovery from the anesthetic. The most pronounced effects of the smooth, gliding movements of the chair-table, even when the older methods of anesthesia were employed, had been a noticeable diminution in the loss of blood and a more satisfactory recovery from the anesthetic. This would seem to show that sudden changes in posture or sudden disturbance of the body, while the patient was under the influence of a general anesthetic, predisposed to shock, the effects of which were manifested both during the operation and during recovery from the anesthesia. After a careful study of this phenomenon they became so much impressed with the value of an elevation of the body from the recumbent to the upright position without jarring that they had constructed a chair-table remodeled to make it possible to accommodate, from the beginning, the most diminutive children, in order to avoid the disturbance of nervous or circulatory equilibrium which was apparently caused in such cases by lifting the body by hand, to place it upon folded blankets so that the head could be raised to the level of the headrest. By the aid of a new attachment all the movements of the body were now made with as great a freedom from jarring and disturbance of balance, with infants and very small children, as had hithertofore been possible only with larger children and adults. The resulting improvement in conditions left no doubt of the accuracy of the observation. They now believed that the movement of lifting the patient from the table or bed to the chair, the jar and jolt of adjusting the body to the seat and back, and the almost unavoidable jarring in bringing the chair to the upright position, gave rise to nervous disturbances, for in no other way could they explain the improvement in the condition of the patient during and after operation since the advent of the chair-table. One full year's experience with this instrument of precision had provided a sufficient basis for the statement that a smooth, jarless elevation of the body, without any disturbances than were absolutely necessary to bend the body from the supine to the sitting posture, must be accepted as of fundamental importance in obtaining ideal results from operation in the upright position. One of the most important and valuable recent contributions to anesthesia methods was the ability to omit or shorten the second stage, or stage of excitement, and they were impressed with the desirability of attaining narcosis without struggle. This could be accomplished with nitrous oxide gas, but with greater ease and certainty with the essence of orange. The discoverer of the remarkable effects of the essence of orange as a preliminary to ether, Gwathmey of New York, had demonstrated the possibilities and had proven to their satisfaction that it greatly assisted in the reduction of shock by shortening the stage of excitement. Anesthesia conducted in this way up to the time of raising the body to the upright position was a contributive factor in reducing hemorrhage, also in reducing the quantity of the anesthetic and in shortening and modifying the after-effects. They were now convinced that shock from the loss of blood and from the anesthetic could be materially reduced by the manner of administering the anasthetic. Irrespective of all other conditions there was a well-defined and never-failing relationship between the degree of skill in which a patient was anesthetized in the upright position and the amount of hemorrhage which occurred during the anesthesia; there seemed to be no question but that hemorrhage was reduced if the anesthetic was smoothly administered, the second stage omitted and the patient brought into surgical anesthesia without jarring or body disturbance of any kind. The preliminary use of nitrous oxide gas or the essence of orange and the drop method of anesthol, followed by the drop method of ether with the open inhaler and later with the Allis inhaler, would insure a prolongation of the anesthesia after the body reached the upright position, a reduction in hemorrhage and also a reduction in the disagreeable sequelæ. Sequestration of the limbs produced a congestive hyperemia and was produced by means of inflated blood pressure cuffs about the thighs and arms; this reduced the amount of blood in the head. Sequestration was first suggested by Dr. R. H. M. Dawbarn of New York in 1907 to reduce hemorrhage in operations upon the head. This sequestration method, in association with the upright position which had been carried out in 58 cases during the past season, reduced still further the amount of the anesthetic required and still further the loss of blood. The average blood loss with the sequestration method, whether applied to arms and legs or legs alone, was far below that which occurred without sequestration, and that certain operations might be rendered practically bloodless by the use of sequestration in the upright position. There did not seem to be any apprehension of secondary hemorrhage when the patient was returned to the horizontal position; after the operations were finished and the bleeding arrested there was no further hemorrhage in this series of cases. To be able to administer a smaller quantity of an anesthetic and obtain a full anesthesia, to see the patient enter the anesthetized state without the stage of excitement, to be able to stop the administration of the anesthetic when the body was brought to the upright position and yet have the anesthesia prolonged enough to permit long operations to be performed, to secure a greatly lessened loss of blood and to insure a reduction in, and in many cases an almost complete abolition of, the disagreeable after-effects, was something of a gain and in a large proportion of cases all these results were obtainable.

Dr. Harmon Smith of New York said that he had seen Dr. Dawbarn operate upon a case in which considerable bleeding was to be expected, but by the employment of sequestration of the lower extremities little or no hemorrhage had resulted. He believed that in the suction employed for the removal of blood in the nasopharynx during the time of removal of tonsils and adenoids, considerably more blood was drawn away than would otherwise happen and that in some anemic children this loss of blood was of serious consequence. If one could lessen the amount of hemorrhage by sequestration it would lessen the obstruction to the operative field and also be of material benefit toward the rapid recovery of the patient after the operation.

Dr. Joseph H. Bryan of Washington, D. C., believed that these adjuncts to anesthesia, especially when they were looking for a serious hemorrhage in the upper air passages and particularly from the upper and posterior sinus, should be employed. He believed that many cases passed away on the table that could be carried along and saved from death and from alarming hemorrhages by these adjuncts.

Dr. James A. Logan of Kansas City, Mo., asked if in all cases secondary hemorrhages occurred, that was, hemorrhages three, four, or five hours after the operation.

Dr. Charles R. Holmes of Cincinnati asked Dr. French what his opinion was as regarded the upright as compared with the horizontal position.

Dr. Thomas H. Halstead of Syracuse, N. Y., said that he had used the table presented by Dr. French and with much satisfaction. In the upright position there was less hemorrhage, but he had not used the sequestration method.

Dr. George L. Richards of Fall River, Mass., said that he had operated on patients in the upright position for a number of years.

Dr. Arthur W. Watson of Philadelphia said he wished to recall the fact that the late Dr. Harrison Allen was an advocate of the upright position in operating on the nose and throat, and during the latter part of his life used that position in all of his operations. The late Dr. Bliss also used the upright position in all his tonsillectomies.

Dr. French, in closing the discussion, said that he thought the patient did as well in the upright as in the horizontal position. Of course this did not apply to all cases. He had in mind the saving of blood, and he wished all present would use this method for the prevention of hemorrhage. Careful as they might be, secondary hemorrhage did occur sometimes after operation. Sequestration of the extremities after the method of Dawbarn had been done without the slightest disturbance, one extremity being sequestrated after the other. It seemed to him to make no difference whether sequestration was followed or whether the patient was placed in the horizontal position. There seemed to be no danger

from secondary hemorrhage in these cases. He found no difference in the hemorrhage so far as the upright position was concerned. The most important thing to consider was the diminution of shock and he was glad to note Crile's brilliant work in this respect.

The Training of the Specialist.—Dr. THOMAS J. HARRIS of New York believed that a concerted advance movement to properly standardize their specialty was essential. The time was now ripe. This had been discussed before the American Laryngological, Rhinological, and Otological Society two years ago and a committee was appointed to consider this matter. A report had been prepared by its chairman, Dr. D. J. Gibb Wishart, and the views therein expressed agreed in the main with those of Dr. Harris. As an outline for a more definite working basis some such plan or scheme of instruction for special work might consist of the following divisions: First, a thorough preparation in the undergraduate medical school; second, a general preliminary training through several years of practice or hospital internship; third, at least six months of special instruction covering not merely the clinical side but the anatomical, pathological, surgical, etc., fourth, eighteen months of internship in a special hospital or in the ear, nose, and throat department of a general hospital; fifth, at the conclusion an examination by a university which should confer upon the successful candidate a postgraduate degree. The committee was strongly of the opinion that the postgraduate instruction should be given in some established university and further that to make the departure a complete success legislation would be necessary. This, when public sentiment had been aroused, there would be no difficulty in securing. Finally, the committee was of the opinion that any success in this advance movement must be the result of concerted action on the part of the several societies representing America and Canada.

Dr. GEORGE L. RICHARDS of Fall River, Mass., said that at the Triological Society he had brought up facts that bore on this line of work. He thought that Dr. Harris's paper was a very timely one and helped to impress upon them that such an outline as had been suggested was very essential. They were aware that such instruction was asked for by the undergraduate student. Many of the students came to the teacher and asked what specialty they should follow, and when they were carefully questioned it would be found that they wished to take up this or that specialty because such and such a practitioner had made a success of it. They looked at it from the commercial point of view. The student was often not willing to take a course in a hospital and to acquaint himself with general medicine. He was not willing to devote one or two years to general practice in order to equip himself as the result of personal contact with patients. The work proposed by Dr. Harris should be insisted upon. They overlooked the fact that some universities required the presentation of a degree such as Ph.D., as being essential before the student was allowed to enter upon a course. In Washington they had found it very difficult to go before Congress and have the ordinary but necessary legislation required even for their own city. They would have to fight to the utmost for medical legislation. Universities could gain considerable assistance by the proper alignment of the different schools in this line of work. Standardization was a very important point.

Dr. H. W. LOEB of St. Louis, Mo., said that in this country there were 150,000 physicians and he hesitated to say how many were qualified to practise medicine in any branch. The requirements to-day were different from those of twenty-five years ago. A few years ago the men with a grammar school education found it easy to undertake the study of medicine. Many of these men, after practising for from five to fifteen years, desired to share in the supposed prosperity of those who specialized; one could not stop that class of men from becoming specialists in this country. In the next twenty-five years the properly prepared physicians would be in the majority. Dr. Loeb said he was heartily in favor of any movement which would improve the situation, but this would be easy when the standard of physicians in this country was equal or superior to that of other countries and where the six weeks specialist was practically unknown.

Dr. BURT E. SHURLY of Detroit, Mich., referred to one meeting which occurred out in the Middle West, where it was stated that out of 1,600 practitioners one-fifth had registered as specialists in the eye, ear, nose, or throat. This did not tend to show any high standardization of their specialty. In order to accomplish what was needed it seemed to him that the formation of the American College of Surgeons was a step in the right direction.

History of a Broncholith, Bronchial Calculus, or Lung Stone.—Dr. WALTER F. CHAPPELL of New York said that laryngologists and rhinologists were frequently consulted for throat cough and some forms of asthma and, for this reason, he wandered into the bronchial region for an opportunity of presenting an unusual case and to show that all causes of asthma were not centered in the nose, nor all throat coughs in the larynx. The patient was fifty-two years old and was attacked first by a severe wheezing which became more severe, and was accompanied by spasmodic attacks of coughing lasting an hour at a time and by intense tickling in the throat; there was little expectoration. There was considerable exhaustion following these attacks. The tickling was below the larynx, and the wheezing in the upper part of the chest in front and behind. She soon raised a small calcareous mass and the tickling was relieved, but the wheezing continued. Soon after she was seized with a great coughing spell and expectorated a large calcareous mass which Dr. Chappell presented. Immediately all wheezing stopped and her breathing became absolutely free. Later another calcareous mass was coughed up. Chemically these masses consisted of phosphate of lime. The history of the patient did not in his mind give any definite clue of her having suffered from the disease which one would naturally believe must have preceded the formation of the numerous calcareous deposits which the patient had in her chest and some of which she expectorated. A careful review of the literature revealed few reports of such cases in the English language, but French and German books reported more cases. Dr. Walter B. James of New York gave him an unreported case which occurred in his practice; Dr. Chappell gave a résumé of the history of this case, which was taken ten years ago. A recent letter to Dr. James stated that the cough and bronchial condition, for which he was consulted, ceased with the expulsion of the stone.

The Removal from the Esophagus of a Plate of False Teeth Embedded for Eighteen Years by Means of an Esophagoscope.—Dr. D. BRADEN KYLE of Philadelphia reported this case, and showed the foreign body. In spite of its size and shape it was very difficult to locate it because of the granulation tissue which had organized into fibrous tissue together with the curvature of the spine as shown in the *x*-ray plate. The patient swallowed the upper suction plate with four attached front teeth while sleeping; inserting his fingers into his throat he was able to touch the plate, but in his efforts to grasp it only succeeded in pushing it down further. The physician who was called in wished to push it down into the stomach, but to this the patient objected. He then went to a hospital where the doctor passed bougies and probangs and assured him that he had never swallowed the plate, or if he had that it was no longer in the esophagus. During the first three weeks following the disappearance of the plate the patient experienced slight pain in the lower part of the neck, at a point where he always felt the object had lodged. After that time there were practically no painful sensations, but swallowing had always been difficult. When solid food was taken it had to be finely ground. For months at a time he only took liquids. The patient was placed on a table with his head well extended over the end, a position very difficult to bring about because of the rigidity of his spinal column. An attempt was made to secure a view of the plate by means of the Kirstein autoscope, but this was found to be too short and the Kahler esophagoscope was used instead. Many attempts were made, but the successful removal of this foreign body was due largely to the fact that the speaker proceeded slowly and made as little trauma as possible in the esophageal structures, and by loosening the foreign body from its fibrous bed, by setting up slight inflammatory action, and then waiting a few days, he was able to remove the plate without much laceration of the structure.

Dr. HENRY L. SWAIN of New Haven, Conn., congratulated Dr. Kyle on being able to recover the teeth after so long a period and also because the patient had not developed any malignant disease or other bad results because of the long stay of the teeth in the esophagus.

Dr. ALGERNON COOLIDGE of Boston congratulated Dr. Kyle on being able to remove the tooth plate without anesthesia. The principal difficulty in the removal of foreign bodies from the esophagus was often a deficiency in armamentarium. To cut tooth plates and similar work required very special equipment. Large esophagoscopes were often of great service. It must always be remembered that the trachea might be compressed from behind by a shifting of the position of a large foreign body, and it was well to have a bronchoscope at hand in case breathing became obstructed.

Dr. D. Braden Kyle of Philadelphia, Pa., said that the curvature of the spine, as shown in the *x*-ray plates in this particular case, rendered it very difficult to pass the esophagoscope. It was only by careful manipulation and continued patience that the operation was successful. The continuous looking through the tube was tiresome to the eye and he had been fortunate in having trained assistants on whose services he could rely.

Preliminary Report Concerning the Passage of Bacteria through the Tonsillar Tissues as Determined by Experimental Research.—Dr. George B. Wood of Philadelphia, Pa., read this paper and presented the following conclusions: From a study of the experiments outlined they found important facts which warranted them at this time to draw the following conclusions:

(1) They found that the tonsils, in the case of the hog were more readily infected by the anthrax bacillus than any other portion of the buccal or pharyngeal mucosa. The clinical history of this disease in the hog showed that in the great majority of idiopathic cases the pharynx was the site of the invasion, and in all of those cases of pharyngeal disease, the tonsils were the portal of entry. In none of his experiments was there any involvement of the pharyngeal or buccal mucosa other than the tonsils. While the culture of anthrax was generally brought into more intimate contact with one of the tonsils, it was impossible to limit the bacilli to the tonsillar surface, and they must have come in contact with a large part of the pharynx. In the inoculation an effort was made to rub the emulsion into one tonsil only, and in one case the lesions were limited to one tonsil; in this case the tonsil affected was not the one on which the culture had been rubbed. (2) The anthrax bacillus penetrated through the crypts and not the surface of the epithelium. (3) The anthrax bacillus probably gained access to the parenchyma of the tonsil by passing through the living, unaltered epithelium, and having gained access through the superficial layers of the epithelium they tended to multiply in the deeper layers and then pass into the interfollicular tissue. (4) The anthrax bacillus penetrating through the living normal epithelium caused devitalization of the tissue, which paved the way for a secondary infection from the staphylococci or other pathogenic organisms. (5) The rapidity of the invasion was influenced both by the virulence of the organism used and by the susceptibility of the individual animal.

After the invasion had actually occurred, the subsequent course of the disease was similar to that found in other tissues. The toxin elaborated by the bacilli caused at first an accumulation of polymorphonuclear cells, and later necrosis of the tissue cells with disintegration of the nuclei. The germinating follicles showed more resistance to the disease than the interfollicular tissue. Associated with the necrotic process was an increase in the number and engorgement of the capillaries, and sometimes there was marked extravasation of the red-blood cells. The anthrax bacilli accumulated in the lymph spaces and also around the blood-vessel walls. In some of the sections examined the bacilli were found penetrating the blood-vessel walls and a few were found actually in the blood current.

Dr. George B. Wood of Philadelphia, in closing the discussion, said that so far as not finding the anthrax bacilli in the main blood-current when they were present in the capillaries was concerned, it must be remembered that in anthrax the bacilli accumulated in the capillaries in dense networks and did not become free in the blood current until the last stages of the disease, when the resistance of the host had been entirely overcome. The danger of infection when experimenting with the anthrax bacilli was not especially great, as they were always wet and could not become disseminated in the air. The cases of anthrax among those who handled skins were due to pulmonary infection by breathing the dry anthrax bacilli, especially the spores. An important extension of this study would be the determining of the resistance of the tonsillar tissues in the various breeds of hogs by the search for antibodies, bacteriolysin, agglutinins, etc., in a large number of tonsils taken from slaughtered animals. This had been suggested by the very different degrees of infection caused in different animals by altogether similar methods of inoculation.

Practically the only fact demonstrated by the present research was that anthrax bacilli would penetrate through the epithelium of the tonsillar crypt more readily than through the surface epithelium of the tonsil or other portions of the pharyngeal mucosa. That the disease having gained access to the tonsil did not advance more readily was a fact which opened up a large field for thought and experimentation

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held May 19, 1913.

The President, Dr. Reynold Webb Wilcox, in the Chair.

A New Water Purifier.—Dr. Thomas Darlington gave a demonstration of a new water filter, one of the important features of which was a special arrangement of two layers of asbestos. Most of the filters on the market, he said, did not strain out bacteria, but, from actual tests made, it had been found that this apparatus would stop the passage of no less than 99.5 per cent. of the bacteria in water. It also completely removed all coloring matter from the water, even aniline dyes, which were exceptionally difficult to get rid of. In addition, it gave a very large flow, a single filter purifying as much as 1,200 gallons an hour. On this account, as well as its other advantages, Dr. Darlington thought it would be particularly useful for troops on the march.

The Sanitary Problems of the Philippines on American Occupancy.—Colonel L. Mervin Maus, Medical Corps, United States Army, read this paper. He said that when the American troops entered Manila they found the sanitary condition of that city similar to that of European cities during the middle ages. After discussing the criticism that had been launched against the government in regard to the great financial cost and loss of life entailed by the war with Spain in the acquisition of Porto Rico and the Philippine Islands, he gave a brief detail of the sociological condition of the natives of those islands, and called attention to the great blessings which the war had conferred upon those peoples; referring particularly to the splendid work of the Army Medical Board in the suppression of yellow fever in Cuba and the special work accomplished in the Philippine Islands by the civil government. He stated that before the Spanish American War few of the natives in the Philippines could read or write, and that their general condition might aptly be compared to that of the semicivilized Indians of Arizona and New Mexico at the present day. Certainly, only a very small number of the people had a liberal education. At the time of the American occupancy there was practically no board of health for the Philippine Islands and but few hospitals, and it was believed that 80 per cent. of the children died during infancy as the result of defective nutrition, cholera infantum, and infantile convulsions. The Insular Board of Health was organized in 1901, and it had revolutionized the sanitary conditions in the city of Manila and throughout the Archipelago. At the end of the first year of the existence of the board the death rate in Manila was reduced 50 per cent. Among the matters included in the work of the board was the creation of laws for the practice of medicine, dentistry, pharmacy, veterinary surgery, undertaking and embalming, compulsory vaccination against smallpox, segregation of lepers, and the organization of provincial boards of health. In 1901 the city of Manila was stricken with a serious epidemic of bubonic plague, and this was combated by the extermination of the rodents of the city. During the campaign 15,000 rat traps were set and 75,000 plates of ratbane exposed every night; which practically exterminated the rats within six months, by which time the bubonic plague had disappeared from the city. During this remarkable campaign it was believed that over eight hundred thousand rats were destroyed, while twenty thousand of the animals were examined microscopically to see whether they were infected or not. Smallpox was one of the greatest menaces to health in the Philippine Islands on American occupancy, and it was commonly found throughout the Archipelago in a virulent form. As a result of a law prescribing compulsory vaccination for the natives the disease had been eliminated from the islands. The vaccination was carried on upon a very extensive scale, and over three millions of the people were vaccinated. The virus employed was made from the heifer of the carabao. Among the most important actions of the board of health was the colonization of the lepers, who amounted to four thousand in number. The Island of Culion was selected for the purpose; it was provided with quarters, hospital, schools, churches, etc., and all the lepers in the islands were sent there. The colony had now been in operation for five or six years and it was believed that within the next generation leprosy would disappear from the Archipelago. In 1903 Asiatic cholera made its appearance in Manila, and very soon it had permeated all the other islands. It was a very difficult proposition to combat this epidemic, on account of the ignorance and superstition of the natives; but it was held in check, and finally, a few years later, completely over-

come. Many radical changes had been made among the Filipinos since 1898 along sanitary, educational, and sociological lines. Boards of health had been established throughout the island, and a campaign of sanitary education introduced which had revolutionized the habits and customs of the people. Artesian wells had taken the place of the infected surface wells in many of the communities, and the health of the natives had been correspondingly increased. Through the beneficence of public school education the vast majority of the coming generation had received a liberal education, and were able to speak English. Athletic sports had been encouraged by the Americans, with resulting marked improvement in the physical condition of both sexes. Tennis and baseball had been accepted as national games, not only in the Philippines, but also in Japan and China. The city of Manila had been immensely improved and now possessed a modern sewer system, new hospitals, magnificent hotels, beautiful parks, and clean streets. Hence it had become the pride of oriental cities, with the lowest death rate of them all. Besides a great university had been established in Manila, with colleges of medicine, pharmacy, veterinary medicine, law, engineering, agriculture, forestry and the liberal arts. A bureau of science had been established, with well equipped chemical and biological laboratories for the study of diseases afflicting man and animals. In addition, the government had constructed a large ice and refrigerating plant in Manila and established a hospital of 300 beds, which afforded ample accommodation for the families of civil employees and the public at large. While the sanitary work in the Philippines had attracted very little attention in the United States, it was believed that in the last analysis it would be found equal, if not superior, to that performed in the Canal Zone; especially when it was appreciated that the great work done there among a population of eight millions of people and an area of one hundred and twenty-five thousand square miles had cost the United States nothing (all the expenditure having been met by the revenues of the colony), while the work in the Canal Zone, with a population of seventy thousand people and an area of three hundred and eighty square miles, had cost the United States Government nearly fifteen millions of dollars. The sanitary and constructive work in the Philippine Islands performed by the Board of Health and the Civil Commission would ever remain as one of the greatest monuments to American intellect and progression that the world had seen.

Observations on Beriberi in Japan and the Philippines.—Major Lewis Hess, Medical Corps, United States Army, in this paper, brought out the following points: (1) Recent investigation into the etiology of beriberi, and observation of the disease among the native troops and other natives of the Philippine Islands and the numerous cases occurring in the Japanese army during the Russo-Japanese war, would indicate that beriberi was due more to lack of nitrogenous food, and a diet largely composed of carbohydrates, than to a specific organism. At least, diet was an important predisposing factor in its causation. (2) While beriberi was apt to occur endemically and epidemically, it was extremely doubtful whether it was contagious, or could be transmitted from man to man. Hence, it should not be classified in the category of infectious or contagious diseases. If beriberi were caused by a specific organism, this certainly could not have any pathogenic action upon healthy and well nourished individuals. It was possible that individuals who subsisted on a diet largely nitrogenous had a natural immunity against the specific organism of beriberi, and that this organism could act only on individuals who had a lowered resistance from the use of food consisting largely of carbohydrates, and in the presence of certain meteorological and other conditions. (3) The results and findings of the United States Army Board of Medical Officers for the study of tropical diseases as they existed in the Philippine Islands, in regard to the influence of rice diet and inanition in the production of multiple neuritis in fowls, and the bearing thereof on the etiology of beriberi, afforded a further proof that the lack of nitrogenous food and the excess of carbohydrates constituted an important factor in its etiology, if not the specific cause, of beriberi. As the result of a series of experiments on chickens, they were able to produce in the birds a multiple neuritis similar to that occurring in human beings suffering from beriberi by feeding them on polished rice; and, on the other hand, were able to cure them by feeding them on the polishings of rice, or the pericarp of the rice. Moreover, fowls fed on undermilled rice (that with some of the pericarp left on) did not become affected with aneuritis. While chickens and other fowls were very prone to be attacked with a general neuritis under certain conditions, it was believed that these experiments pointed strongly toward rice as constituting an important factor in the causation of beriberi. By way of confirmation of the experiments the rice in the ration of the native scouts in the Philippine Islands (of which it largely consisted) was changed to the native rice, which was undermilled, and the result was the complete disappearance of beriberi among them. (4) Beriberi had always been classed as an unpreventable disease, and was so considered by the Japanese, who reported over 97,000 cases in their army during the Russo-Japanese war. It should now be classed as a preventable disease, and there was no excuse for its occurrence to any extent among troops, any more than there was for that of smallpox, typhoid fever, dysentery, cholera, and similar diseases which in the past had at times rendered armies almost ineffective and had often been a potent factor in deciding results between contending armies. As a matter of fact, Major Hess said, there was reason to believe that the wide prevalence of beriberi in the Japanese army had had a very considerable influence in bringing about the termination of the late war. In regard to the very considerable immunity from typhoid fever among the Japanese troops, about which so much had been said, this was practically due to the simple facts that the Japanese were extremely fond of tea (the water used thus being boiled) and of cooked foods; and the same thing was true of the Russians. On the other hand, our soldiers in the Spanish-American War did not like tea and drank much water, while they preferred raw to cooked foods. There was, however, some typhoid fever among the Japanese in the war with Russia; the number of cases, according to their own reports, amounting to more than 9,000, while there were over 4,000 deaths, a mortality of nearly fifty per cent. Among the Russians there were a little over 10,000 cases, but only about 1,000 deaths, a mortality of one-fourth that among the Japanese.

Dysentery in the Tropics.—Major Eugene R. Whitmore, Medical Corps, U. S. Army, in this paper, said that this disease was one of the leading causes of death in the tropics. It had been stated, with truth, that it was a more potent factor in the death rate than malaria, though the latter caused more illness. Two types of dysentery were recognized, amebic and bacillary, and these two types differed in cause and morbid anatomy, and required different treatment. Amebic dysentery was endemic and did not ordinarily give rise to epidemics; bacillary dysentery gave rise to extensive epidemics. Amebic dysentery was due to a protozoon; bacillary dysentery was due to a bacillus. In amebic dysentery the process began in the submucosa, from the specific tissue-destroying properties of the amebæ which had traveled in through the mucosa; bacillary dysentery was a diphtheritic or croupous process, involving the intestinal mucosa, while the submucosa was only secondarily involved. Liver abscess was a frequent complication in amebic dysentery, but very rare in bacillary dysentery. Amebic dysentery tended to become chronic, with frequent relapses; bacillar dysentery was a self-limited disease, with a tendency to complete recovery. Ipecac, in the form of emetin, was a specific in amebic dysentery, while a specific antitoxin and bacterial serum gave the best results in the treatment of bacillary dysentery. The amebæ were found only rarely in the small intestine, but sometimes might be confined to the appendix alone; which would explain the presence of amebæ without dysentery. The dysentery bacilli frequently got into the small intestine. Hepatic abscess was the most common complication of amebic dysentery, and in all the ulcerations in this affection, whether in the liver or the intestines, there was a striking absence of purulent inflammation. The amebæ might travel not only into the liver, but also into the pleural cavity and elsewhere. Still, liver abscess was the greatest danger to be apprehended, although perforation of the bowel was not uncommon. The symptoms of the two forms of dysentery, the amebic and the bacillary, were the same; so that clinically it was impossible to make a differential diagnosis between the two. From an examination of the stools it was never safe to say that amebæ were present unless one could discover amebæ actually moving. Ipecac had long been highly esteemed in the treatment of dysentery, but, on account of the difficulties met with in connection with its administration, the remedy was often almost as bad as the disease. The attempt had been made to employ de-emetized ipecac, but this was found to have no effect in dysentery. Vedder had demonstrated, however, that emetin killed cultures of amebæ, and this principle of the drug was now commonly used in the treatment of amebic dysentery. It was preferably given hypodermically in

doses of from 1/10 grain to 1 grain, once daily. Allen had administered it in doses up to four and two-tenths grains. In the bacillary type of dysentery there were two groups. The bacillus of the first was discovered by Shiga, the Japanese investigator, in 1898, and in 1900 Flexner confirmed this and announced a second group; though at first he believed that the bacillus he had discovered was identical with Shiga's. The Shiga group was now recognized as the toxic group, and the Flexner as the atoxic group. The latter, in which there were several strains, was not really atoxic—it was simply less toxic than the Shiga group. The morbid anatomy and symptoms, as well as the treatment, of the disease were the same in the two groups, but the Shiga type of dysentery was the more fatal. Amebic dysentery was usually subacute from the first and tended to progress indefinitely, and in this respect was very different from the bacillary form, which was an acute affection, and, as had been mentioned, was self-limited and had a tendency to complete recovery. In some instances, however, the latter became subacute or chronic, and this was probably the condition in the cases of chronic diarrhea which were noted among the soldiers of the Civil War. There were sometimes joint complications, somewhat of the nature of general arthritis, but, in contrast to amebic dysentery, peritonitis, bowel-perforation, and liver abscess were rare. From the intoxication of the system, neuritis was not uncommon. The bacilli could be isolated from the stools and also from the superficial part of the intestines. In this form of dysentery ipecac was of no practical value. While the disease was self-limited and essentially tended to recovery, in the Shiga type there was a mortality of from twenty to sixty per cent. No medicinal agent seemed to have any control over bacillary dysentery, but very good results have been obtained from the use of serum therapy. The remedies of this class employed were Shiga's bactericidal serum and Rosenthal's antitoxin and bactericidal serum. The speaker said he could not see that intestinal irrigation was of much benefit in acute cases or in the early stages of amebic dysentery, but thought it might be of value in chronic cases.

Dr. NATHAN S. JARVIS referred to the views on the tolerance of the white man in the tropics expressed by the noted sociologist Benjamin Kidd in his book entitled, "The Control of the Tropics," which was published no longer ago than 1898. It was then the practice in the British army to allow officers who had served one year on the west coast of Africa a year's leave, and this was also the rule in regard to those serving in India. This was on account of the conditions, so unfavorable to the white race, prevailing in those tropical regions. Now, however, it was possible for the white man to live indefinitely, and live comfortably, in the tropics. This was very largely owing to the splendid work accomplished by the medical officers of our army, and the praise which was their due should be unstinted. At the same time, it should not be forgotten that in recent years the army surgeons had had the warm cooperation of the line officers, and such results could not have been attained without this. Formerly the case was different, and he could well remember that twenty years ago, when he himself was in the army medical corps, it was almost impossible to get a line officer to take any interest whatever in sanitary matters. Panama might be cited as an instance of the marvelous change which had been effected. In regard to the freedom from disease of the Japanese in the late war with Russia, this had undoubtedly been exaggerated, but he would say, in justice to some of those who had extolled the sanitary triumphs of the Japanese, that they had been deceived by the latter; for the reports which were furnished to them were both very incomplete and very erroneous. We should not lose sight of the fact, however, that the discipline in the Japanese army was really wonderful. In the case of volunteers, such as our army was largely composed of in the Spanish-American War, it took a year or two before the men could be depended upon to obey orders in a reasonably satisfactory manner. The results accomplished by the Japanese were due to their discipline.

Acute Pemphigus Complicating Typhoid Fever.—A. Reuter reports the case of a fifteen-year-old girl in whom there appeared on the sixteenth day of an attack of typhoid fever a number of pemphigus-like lesions. These were round, of a size varying from that of a pea to that of a walnut, and consisted of blebs filled with a clear fluid. The base of the lesions, at first light red, later became gangrenous. The lesions appeared on the back and on the leg. Coincident with the recovery from the typhoid fever the pemphigus also got better, but left round scars.—*Arch. f. Derm. u. Syph.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

April, 1913.

PATHOLOGY.

1. Give a description of adenocarcinoma under the microscope.
2. Describe *B. diphtheriæ*.
3. Exclusive of changes in the intestine what is the morbid anatomy of typhoid fever.
4. What conditions result from disease of the pituitary body?
5. Name some of the common fluids used for hardening tissues preparatory to section, with the strength ordinarily used.
6. Describe the phenomenon known as inflammation.
7. Give the morbid anatomy of acute endocarditis.
8. Describe the morbid anatomy of acute lobar pneumonia.
9. Discuss the cause of death from burns.
10. Discuss anaphylaxis.

OBSTETRICS.

1. Name possible sources of puerperal hemorrhage and treatment of each.
2. What would lead you to suspect extrauterine pregnancy?
3. In breech presentation describe the different methods of delivering the aftercoming head.
4. You are called upon to take care of a woman in labor; describe how you would proceed to sterilize your own person.
5. Give symptoms of rupture of the uterus.
6. How may you prevent perineal lacerations?
7. Outline treatment for the prevention of ophthalmia neonatorum.
8. Write two pages on the preventive treatment of eclampsia.
9. Give the treatment of eclampsia?
10. Give the mechanism of L. O. A.

SURGERY.

1. Describe the fractures of the elbow and the method of examination.
2. Give the symptoms and diagnosis of fracture of the surgical neck of the humerus.
3. Give the symptoms and complications of fracture of ribs.
4. Define toxemia, septicemia and pyemia.
5. Give the symptoms and causes of a subphrenic abscess.
6. Give the symptoms and diagnosis of tuberculous arthritis.
7. Give the symptoms and etiology of varicose veins.
8. What are the causes and symptoms of acute intestinal obstruction?
9. Describe the symptoms of abscess of the liver.
10. Discuss benign and malignant tumors of the breast.

ANSWERS.

PATHOLOGY.

1. *Adenocarcinoma* "is characterized by irregular or tubular cavities, paved with one or more layers of cylindric cells, and separated by a stroma which may be fibrous, embryonal, or mucous. In structure it occupies an intermediate position between the simple adenoma and true cancer. The cylindric cells are similar to those which cover certain mucous or glandular cavities, and are always implanted perpendicularly to the wall. The epithelial elements are similar to those of the mucous membrane from which they grow, but differ microscopically from the normal mucous membrane in the absence of a basement membrane (membrana propria). The slower the growth, the more typical the gland formation; in rapid growths and recurrences the cells are small and the lumina imperfect. The growths are soft, and often of a gelatinous consistence. On section they present a soft, watery appearance. The most common forms of degenerative changes are mucoid and colloid." (Coplin's *Pathology*.)

2. *The characteristics of the bacillus of diphtheria:* "The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly, or in pairs,

or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aerobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

3. In addition to the changes in the intestine, there may be: Enlargement of liver and spleen, infarction or rupture of spleen, abscess of liver, cloudy swelling or degeneration of kidneys, nephritis, ulceration of larynx or pharynx, edema of the glottis, pneumonia, congestion or gangrene of lung, endocarditis, myocarditis, pericarditis, fatty degeneration of the heart, endarteritis, thrombus, or embolus.

4. Diseases of the pituitary body may result in gigantism and acromegaly.

5. *Hardening fluids:* Alcohol, 95 per cent.; formalin, 4 per cent.; potassium bichromate, 2.5 per cent.; bichloride of mercury, 5 per cent.; osmic acid, 1 per cent.

6. "*The phenomena of inflammation* are dilatation of the arterioles, capillaries, and small veins. At first the blood current is quickened, then retardation occurs, and may progress to stasis and thrombosis. During this time exudation of plasma and white corpuscles from the small veins, and perhaps the capillaries, is going on. The fate of the white cell may be either to break up and set free prothrombin, or to act as food for connective-tissue cells, or to act as a phagocyte and be transformed into a pus corpuscle. Red corpuscles may be exuded and broken up, setting free their coloring matter. The prothrombin of the white cells unites with the calcium chloride of the plasma, and forms thrombin, or fibrin ferment, which acts upon the fibrinogen of plasma to form fibrin. The tissues are, thus invaded with numbers of leucocytes. In bacterial inflammation a varying portion of the tissues is killed by the toxins produced, and is either replaced by a mass of small round cells, or liquefied into pus. In the latter case it is surrounded by a ring of small round cells. The connective-tissue cells absorb the leucocytes, and new vessels are formed, thus constituting repair. In nonbacterial inflammation, exudation may separate layers of cells to a large extent and form blebs. In chronic inflammation the formation of new fibrous tissue is the chief part of the process." (*Aids to Surgery.*)

7. "*Acute simple endocarditis* may be prenatal as well as postnatal. In the former class of cases, the right side of the heart is usually involved, while in those instances observed after birth, the disease is most often limited to the left side. While the disease may attack the entire lining membrane of the heart it is especially marked at the valvular portions of the endocardium. The earliest change is that of hyperemia of the membrane rendering it red and swollen. As the inflammatory exudate is thrown out the surface of the valves become roughened and warty excrescences are formed. These verrucose formations are to be found on the auricular surface of the mitral valve and on the ventricular surface of the aortic valve at the line of contact of their leaflets, usually from 1 to 2 m.m. from their free margin. These vegetations are produced by a proliferation of the cells of the adventitia and of the external connective tissue; fibrin from the blood is deposited on the formations, thus serving to increase their size. The excrescences are friable and may be easily detached or broken off and carried in the blood stream as emboli, to various parts of the body, particularly the left side of the brain, the kidneys, and the spleen. If retained in position, fibrous tissue is eventually formed; the valves become thickened and contracted, producing chronic endocarditis. The leaflets may then become the seats of various infiltrations." (Hughes' *Practice of Medicine.*)

8. ACUTE LOBAR PNEUMONIA. "It is convenient to describe four stages, those, namely, of (1) hyperemia or engorgement, (2) red hepatization, (3) gray hepatization, and (4) resolution. *First stage or splenization.*—The lung is injected, dark red, and heavy, and pits under the finger; on pressure, there exudes a frothy serum tinged with blood and slightly aërated. The lung still floats in water. *Second stage or red hepatization.*—The part involved is solid and friable, presents a granular or red granite appearance, and sinks in water. The alveoli are filled with a coagulated exudation, which shows under the microscope fibrin, leucocytes, red corpuscles, proliferated alveolar epithelium, and pneumococci. *Third stage or gray hepatization.*—The lobe has now the appearance of gray granite, the lung substance is softer and more friable; on pressure, a dirty purulent fluid exudes. The gray appearance is due to four factors: (1) Decolorization of the red blood corpuscles; (2) obliteration of the alveolar blood vessels from pressure; (3) fatty degeneration of the coagulated material; (4) great infiltration of leucocytes. A more advanced stage, in which the lung tissue is bathed in purulent fluid, is known as purulent infiltration. It is probably inconsistent with life. *Fourth stage or resolution.*—Resolution of the inflammatory exudation is brought about principally by absorption (autolysis), but partly by liquefaction and expectoration. Pneumonia may affect a lobe, or the whole of a lung, or it may attack both lungs. Double pneumonia occurs in about 10 per cent. of cases. Different parts of the same lung may at the same time show different stages. There is always some degree of pleural inflammation over the affected area. Moderate enlargement of the spleen is very common." (Wheeler and Jack's *Practice of Medicine.*)

9. *Death from burns* may be due to shock, to exhaustion, to perforating ulcer of the duodenum, or to the absorption of toxic substances. Just why there is ulceration of the duodenum is not determined; possibly it is due to thrombosis of some blood vessel, followed by digestion by the gastric juice.

10. *Anaphylaxis* is a condition of supersensitization induced by the injection of a serum. It is the opposite of prophylaxis, and in place of rendering the person injected immune, the serum has made him particularly susceptible. It has been followed in some instances by alarming symptoms, such as heart failure, collapse, convulsions, and coma.

OBSTETRICS.

1. *Puerperal hemorrhages* may be due to: Retained secundines; displaced uterus; displaced thrombi; fibroid tumors. In a general way, the cause should be removed if possible. The ordinary so-called post-mortem hemorrhage is managed as follows: Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot, can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging with gauze of uterus and vagina may be necessary. Whatever is done must be done promptly, and everything likely to be needed for this emergency should be prepared beforehand in every labor.

2. In *extrauterine pregnancy,* there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage.

3. *Extraction of the after-coming head:* "If the arms are extended by the side of the child's head, they should be delivered first. The posterior arm is located by the position of the trunk and shoulders. To deliver the right arm, the child's ankles should be grasped with the left hand, and the body raised upward and outward over the mother's right thigh. The fingers of the right hand are passed along the posterior surface of the arm beyond the elbow. The fingers are hooked in the elbow, and traction is exerted; the forearm is then delivered by extension. The left arm is delivered in a similar manner. In the *Wiegand-Martin method* extraction of the after-coming head is effected by the insertion of the index finger of the supinated right hand into the child's mouth and making traction upon it, while pressure is exerted through the abdominal wall by the left hand. In the *Mauriceau* or *Veit-Smellie method,* in addition to the right hand index finger in the mouth, the left hand is also introduced into the vagina, along the back of the child, the middle finger presses against the occiput, while the remaining fingers exert traction over the clavicles. In the *Prague method* the child's ankles are grasped in the right hand, the fingers of the left are flexed over the clavicles, and traction is made. In these methods, when the perineum is distended, the child's body is raised toward the mother's abdomen. *Forceps* may be applied after the child's body has been raised and traction made in the direction of the axis of the parturient canal." (*Pocket Cyclopedia.*)

4. In addition to the bath, clean clothes, and other details which may be taken for granted in persons of refinement, the physician should, before making a vaginal examination, carefully cleanse his hands, as scrupulously as if he were about to undertake a major operation. The hands should be scrubbed for at least five minutes with hot water, soap, lysol, and a nail brush that has been boiled or soaked for some time in an antiseptic. Special care must be given to the nails and nail-folds. The hands should then be soaked for three minutes in an antiseptic solution;

such as bichloride of mercury 1:1000. This is followed by another washing in sterile water. Rubber gloves that have been boiled and kept sterile and a sterile gown add to the safety of the patient.

5. RUPTURE OF THE UTERUS. "When rupture actually occurs the typical symptoms are a sudden, sharp pain in the womb (caused by its tearing), sometimes accompanied by an audible noise; sudden and simultaneous cessation of labor pains; a sensation as if warm fluid (really blood) were being diffused into the abdomen; violent shock and collapse, indicated by pallor, feeble and frequent pulse, cold extremities, fainting, hurried respiration, vomiting, etc. (usually due to hemorrhage into the peritoneal cavity). On vaginal examination the presenting part of the child is found to have receded from its former situation, owing to partial or complete escape of the fetus through the rent into the abdominal cavity, where, by abdominal palpation it may be felt as an irregular-shaped, movable tumor, more or less distinct from another tumor formed by the partially contracted uterus. Blood may or may not escape from the vagina. A loop of intestine may prolapse through the rent and be found by vaginal examination." (King's *Obstetrics.*)

6. *Perineal laceration may be prevented:* By making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; by securing expulsion of the head between the pains; by the judicious use of an anesthetic.

7. *Prevention of ophthalmia neonatorum:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediatey after birth.

8 and 9. ECLAMPSIA.—"*The prophylactic treatment* consists in frequent and regular examination of the urine. After the first appearance of albumin, daily quantitative examination of the urine should be made. The diet should be milk; the bowels should be kept freely open by means of calomel and salines; the skin should be kept active by hot baths, followed by vigorous rubbing. Diuretics, such as Basham's mixture, digitalis, and caffeine should be administered. During pregnancy, if the percentage of albumin increases in spite of the treatment, abortion or induction of labor is indicated.

"*The treatment of the attack* consists of the administration of chloroform by inhalation, chloral hydrate (gr. 60) by enema, and the fluidextract of veratrum viride hypodermically (gtt. 15 followed by gtt. 5, repeated frequently enough to keep the pulse at about 60 beats a minute), to control the convulsions, and free purgation by croton oil (gtt. 2, or 3, in sweet oil or glycerine), free sweating by the hot pack, and sometimes depletion by venesection to eliminate the poison. The after-treatment consists of free purgation by the salines, restriction of diet, and later the administration of tonics and stimulants. The obstetric treatment is usually noninterference." (*Pocket Cyclopedia.*) Sometimes *accouchment forcé* is indicated.

10. The mechanism of labor in L. O. A. positions consists of the stages of: Flexion, descent, internal rotation, extension, and restitution. Descent is going on all the time; the other movements are added to it. For details of each of these stages some textbook on obstetrics must be consulted.

SURGERY.

1. "In examining an injury to the elbow, the injured side should be compared with the uninjured. The two condyles and the tip of the olecranon should receive first attention. During extension they form one line; during flexion they form a triangle of which the apex or olecranon is toward the hand. The head of the radius should be felt just below the external condyle. When the arm is flexed to a right angle, a ruler placed along the back of the arm does not touch the olecranon. The forearm is naturally in a position of slight abduction relatively to the arm.

"*Supracondyloid fracture* resembles backward dislocation of the radius and ulna, but (1) the relative positions of the bony points are unaltered; (2) the arm is shortened; (3) the projecting end of the upper fragment is felt above the crease of the elbow; (4) the deformity is reduced with crepitus, but readily reappears. If there is much swelling, it is impossible, without a skiagram, to come to a proper conclusion. Sometimes the lower fragment is displaced forward.

"*T-shaped fracture* is the result of direct violence, and consists of a transverse supracondyloid wtih a vertical fracture running into the joint and separating the condyles. The condyles are widened, and can be moved on each other; great swelling comes on rapidly.

"The *condyles* may be broken by direct violence. Fracture of the external always involves the elbow joint. Abnormal mobility and crepitus distinguish fracture of the condyles. Fracture of the internal condyle may or may not involve the joint.

"The *olecranon* is usually broken by direct, sometimes by muscular, violence. If separation is complete, the upper fragment is drawn up; if the fibrous expansion of the triceps is untorn, there is no displacement. The base of the olecranon is the usual site of the fracture. There is inability to extend the forearm, and effusion of blood into and around the joint quickly follows.

"The *head of the radius* is broken by direct violence or in connection with dislocation. Separation of the epiphysis occurs in children. If the head is completely detached, it does not move with rotation of the lower fragment, and crepitus is felt." (*Aids to Surgery.*)

2. Fracture of the surgical neck of the humerus shows a depression below the shoulder, shortening of the limb, and well marked crepitus on rotation. The lower fragment is generally drawn up. The general symptoms of all fractures are, of course, present: History of injury, disability, false motion, pain, and constitutional effects.

3. Fracture of the ribs produces pain which is increased during inspiration; and crepitus may be heard with the stethoscope. If the sternum is pressed toward the spine pain is felt over the site of the fracture.

The complications that may follow fractured ribs are: "Additional injury, making the fracture externally or internally compound; laceration of the pleura, pericardium, heart, lung, diaphragm, liver, spleen, or colon; rupture of an intercostal artery; hemothorax; cellular emphysema; pulmonary emphysema; pneumothorax; pyothorax; traumatic pleurisy; pneumonia; bronchitis; congestion or edema of the lungs." (Da Costa's *Surgery.*)

4. *Toxemia* is due to absorption of toxins only, and is characterized by a persistent high temperature, relieved at once by removing the source of the poison.

Septicemia is due to organisms multiplying in the blood, and characterized by a maintained high temperature, but not relieved by getting rid of the original source.

Pyemia is due to particles of blood-clot carrying organisms to parts distant from the original source, and there setting up abscesses. It is characterized by rigors, very high temperature, sweatings, and big remissions of temperature.

5. *Subphrenic abscess:* "A subphrenic abscess is a collection of pus beneath the diaphragm. The pus, as a rule, occupies a part of the lesser peritoneal cavity; in rare instances it is extraperitoneal (when it is of renal origin); in some cases it is contained in the area between the diaphragm, cardiac end of the stomach, and liver or spleen. It is an unusual thing for such an abscess to break into the general cavity of the peritoneum, but it may break into the pleural sac.

"*Causes:* Perforation of a gastric ulcer, perforation of the gall-bladder or gall-ducts, ulceration of the duodenum, diseases of the liver, spleen, pancreas, intestine, appendix, or kidney, hydatid disease, internal injury, metastasis, external injury, caries of rib, or disease of the pleura may be responsible for a subphrenic abscess.

Symptoms: "There are the constitutional symptoms of suppuration and a swelling in the subdiaphragmatic region, these symptoms ensuing upon one of the causative conditions before mentioned. In many cases the abscess cavity contains gas as well as fluid. Empyema and subphrenic abscess resemble each other. In empyema the upper limit of the fluid is concave; in subphrenic abscess it is convex. In empyema the flow of pus through an aspirating needle will be most marked during inspiration; in abscess during expiration—the same is true of the rush of gas. In empyema the needle does not oscillate; in abscess it does. The fact that an abscess contains gas is shown by the existence of a tympanic percussion-note over a part of the cavity and an alteration in the area of tympany with an alteration in the position of the patient. An abscess of the liver does not contain gas and alters decidedly the outlines of the organ." (From Da Costa's *Modern Surgery.*)

6. *Tuberculous arthritis.* "In the early stages the signs are not at all well marked, especially in those where the primary stage is osseous, and consist of slight aching after use. Soon, however, the cardinal signs appear: (1) Increased heat over the joint; (2) the presence of some fluid in the joint; (3) impaired mobility; (4) *wasting of the muscles which move the joint.* The joint is usually maintained in the position of ease, viz., slightly flexed. In the late stages abscesses form, and the pain becomes severe, even to 'starting pains' at night. If the abscesses burst and are allowed to become septic, a hectic temperature follows, and amyloid degeneration may lead to death from exhaus-

tion. The joint itself may be disorganized, the relaxation of the ligaments allowing dislocation to occur." (*Aids to Surgery.*)

7. VARICOSE VEINS. *Etiology:* Overdistention caused by long standing; pressure from garters, tumors or pregnancy; failure of the valves in the veins; congenital over-development of the veins. *Symptoms:* The veins are prominent, tortuous, and may be painful; the skin may be discolored; aching and a tired feeling are observed in the affected part; edema, congestion, ulceration, and eczema may result.

8. *Intestinal obstruction* may be caused by: Strangulation, kinking, volvulus, foreign bodies, intussusception, stricture, fecal accumulation, and tumors either within or outside the bowel.

STRANGULATION.	INTUSSUSCEPTION.	TWISTS (VOLVULUS)
Subjective Symptoms.	*Subjective symptoms.*	*Subjective Symptoms.*
1. Generally occurs after age of 20.	1. Most frequent in childhood.	1. Most frequent after age of 30.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse.
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal; recurs less often than in strangulation.
4. Constipation complete.	4. Frequent diarrhea, passage of bloody mucus.	4. Constipation complete.
Objective symptoms.	*Objective Symptoms.*	*Objective Symptoms.*
1. Temperature often subnormal.	1. Temperature normal or subnormal.	1. Temperature slightly elevated.
2. Location in small intestine.	2. Localization in small intestine; bowel frequently protrudes at rectum.	2. Location, small intestine; abdomen often protrudes, in certain areas giving dullness on percussion.

—(*Pocket Cyclopedia.*)

9. *Symptoms of abscess of the liver:* Bulging in the right hypochondrium; a dull, aching pain over the liver; either jaundice or a muddy color to the skin; auscultation may give crepitations or friction sounds; pain in right scapula; increased area of liver dullness; fever and digestive disturbances are generally present; the *amœba coli* may be present in the sputum; loss of flesh, strength and appetite will be noticed.

10. Benign tumors of the breast are fibroma, adenoma, cystadenoma, lipoma, myxoma, and enchondroma. It is generally believed that benign tumors may become malignant. The malignant tumors are sarcoma, and carcinoma. It is of the utmost importance that the presence of a tumor be recognized at an early date, and in case of doubt as to the character of a tumor it should be considered malignant until it is proved to be otherwise. "If the mistake is made of regarding an innocent tumor as malignant the woman loses her breast. If a malignant tumor is regarded as innocent, the woman loses her life." Benign tumors should be removed; malignant, if operable, require entire removal of the breast and neighboring lymphatics.

The Genital Glands and the Dental System.—At the Academy of Sciences M. R. Robinson of Paris recently made a communication on the perfect preservation of the teeth in seven male donkeys aged between 10 and 14 years. These animals, which had been used in the experiments of Professor Lannelongue, were insusceptible of sexual excitement. Their food was hay. On the other hand, a young cryptorchid *griffon*, a very salacious beast, upon which the author had made a necropsy, had lost all its teeth when quite young. Toothache is said to occur in young masturbators, and it appears that true eunuchs have fine teeth, and the author concludes that a physiological relation exists between the genital glands and the dental system. The old belief of the effect of gestation upon the teeth may thus be true. As a result of his clinical observations, M. Robinson is satisfied that in diabetes and tabes it is through the intermediary of the genital glands that the teeth become worn, carious, or simply fall out.—*The Lancet.*

Therapeutic Hints.

Prescriptions for Dysmenorrhea.—Fritsch recommends the following:

℞ Tinct. opii,
Tinct. belladonnæ,
Tinct. hyoscyami,
Tinct. stramonii,
Tinct. valerianæ, āā. 3 grams.

M. et Sig: Twenty drops three or four times a day.

Chrobak favors the use of the following simple formula:

℞ Tinct. castorei, 10 grams,
Tinct. nucis vomicæ, 3 grains.

M. et Sig: Ten drops t. i. d.

Fellner has reported good results from the following:

℞ Fl. extr. hydrastis canadensis,
Malaga wine, āā. 30 grams.
Syr. cinnamon, 10 grams.

M. et sig: One teaspoonful every two to four hours.

The Treatment of Freckles.—Haldin Davis states that these dermatoses of the face may be bleached with various lotions of which the active principles differ widely. A simple alkaline lotion may be employed as follows:

℞ Potass. acetat., gr. xv,
Aquæ destill., ℥ jss,
Alcoholis, ℥ ss,
Ol. rosæ, ad lib.

Or a more elaborate lotion may be used, *e.g.*

℞ Potass. carb., gr. clx,
Potass. chloridi, gr. lxxx,
Borac. venet., gr. xxx,
Aquæ rosæ,
Aq. naphth., āā. ℥ jss,
Sacch. alb., gr. dcxx,
Glycerini, ℥ vii.

This is to be painted on.

Mercury in some form is the active ingredient in many preparations, as in the following ointment:

℞ Hydrarg. ammoniat.,
Bismuth subnitrat., āā. gr. lxxx,
Glyceriti amyli, ℥ vi.

Mercury may be prescribed in a lotion as follows:

℞ Hydrarg. chlor. corrosiv., gr. vii,
Zinci sulphat., gr. xc,
Amygdalæ, gr. lx,
Aquæ rosæ, ℥ viii.

To compound this an emulsion must first be made with the almonds and the rose-water; the mercury is then dissolved therein and the zinc sulphate is added.

Peroxide of hydrogen is frequently used. It may be prescribed in either of the two following mixtures:

Aquæ hydrogenii dioxidi (10 vols.),
Liq. ammon. dilut., āā. ℥ ss.

or

Aquæ hydrogenii dioxidi (10 vols.),
Infus. hamamelidis (B. P.), āā. ℥ ss.

All of these lotions must be applied cautiously, dabbed on with a small pledget of absorbent cotton.

For very dark freckles the radical treatment is to touch them with pure carbolic acid on the end of a match. This has the disadvantage of causing the formation of a slight scab for a few days.—"Skin Diseases in General Practice."

A CONTRIBUTION TO THE STUDY OF CHRONIC INTESTINAL STASIS.

By WILLIAM SEAMAN BAINBRIDGE, Sc.D., M.D.,

NEW YORK.

PROFESSOR OF SURGERY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL, ETC.

Introductory Remarks.—The hard-and-fast division of diseases into functional and organic, and into metabolic and microbial, no longer holds. "Idiopathic," a term formerly used with such impunity, and now generally accepted as signifying ignorance of the etiology of a given malady, is fast becoming obsolete. The trend of modern medicine is to consider so-called functional affections as way-stages to organic disease, and to trace the given conditions back, through the factors which initiated the functional derangement, to the underlying cause or causes of the actual organic disease. We hear much more, today, of toxins—poisons produced by germs—than of the germs themselves; more of bacterins—substances introduced into the organism for the purpose of producing immunity—than of a mysterious, inherent capacity to resist disease.

Happily, we are, as a profession, gradually getting back to causal factors. The fallacy of regarding one effect as the cause of another is slowly but surely disappearing. Constipation, for example, is no longer regarded as a disease, but as an indication of an underlying pathological condition. Indeed, in no department of medicine and surgery is this "back to the cause" movement more noticeable than is that which deals directly with the gastrointestinal tract.

The pioneer in this hitherto largely neglected field is unquestionably W. Arbuthnot Lane, of London. In the face of skepticism, even of ridicule, he has pressed forward in the work of discovering first causes. He has demonstrated clearly that in health-maintenance the question of prime importance is body-drainage—the non-absorption of poisons, and the elimination of whatever poisonous matter may be produced within the alimentary canal, before there has been inaugurated a vicious cycle of events which may be the forerunner of disastrous end-results. Lane and his followers have thus focused attention more directly upon the previously obscure phenomena of intestinal stasis, and have offered a plausible explanation of the underlying causes which have led to the evolution of what have been called "the protean symptoms in a large group of patients who have received much treatment and little benefit from the medical profession and who have been exploited by the dietetic faddist and the charlatan."[1]

During the past six years it has been my good fortune to come into personal touch with Mr. Lane, to examine many of his cases before operation, to see him operate upon them, and to watch the after-course of the condition. While we may not accept all his views with reference to the relationship between intestinal stasis and tuberculosis, cancer, rheumatism, and other diseases, his contentions concerning the actual mechanical conditions existing in the abdominal cavity, as indicated by clinical symptoms, demonstrated by *x*-ray findings, and established by laparotomy, are being verified over and over by those of us who are following his lead in this field of surgical diagnosis and treatment.

Intestinal Obstruction.—When Mr. Lane first set forth his views concerning intestinal stasis, and attributed this slowing of the drainage current to the abnormal fixation of certain portions of the canal, with ptosis on either side of the fixed point, many were inclined to pass over his contentions as being merely reiterations of well-known and long-established manifestations of chronic intestinal obstruction. Indeed, many distinguished surgeons in Europe and America still disavow belief in the existence of any of the types of Lane's kinks, acknowledging inability to recognize them if they have been present in any of their subjects.

The symptomatology, diagnosis, and treatment of the various types of acute intestinal obstruction may be said to have long been matters of general knowledge. The existence of chronic intestinal obstruction has also long been accepted as a possible contingency. It was left, however, to Mr. Lane to establish the fact that many of the factors concerned in the production of the various types of chronic intestinal obstruction are associated with, or perhaps are dependent upon, an already existent chronic intestinal stasis, and that they are, in reality, *end-results* of such a condition.

A notable example of what Mr. Lane has designated as the end-result, and which is catalogued by others as a causative factor in the production of chronic intestinal stasis, is cancer—cancer of the stomach, intestine, biliary ducts, or pancreas. This gives an excellent illustration of the sequence of events as Mr. Lane understands the matter. As pointed out in a previous communication,[2] the correctness of this theory of the cause of visceral cancer cannot be proved or disproved at this stage of our knowledge of malignant disease. The theory is worthy of further consideration, however, and, pending proof or disproof, it should be borne in mind in all cases of chronic constipation, autointoxication, and other obscure conditions seemingly having their origin in defective function of some portion of the gastrointestinal tract. It should be borne in mind particularly, in all cases of "visceroptosis," of "floating kidney," of "gallstones," of "duodenal ulcer," of "mucous colitis," of "pericolitis," of "chronic appendicitis," etc. It should not be forgotten in the group of conditions to which the term "protein diseases" has been applied,—a term used, as Vaughan[3] has pointed out, "to cover the

majority of bacterial and protozoal diseases, and many of those hitherto regarded as autogenous."

Mechanical Basis of Intestinal Stasis.—It is not the purpose of this paper to deal with the general subject of ptosis of the abdominal viscera, its entire symptomatology, its sequelæ, or its treatment. A large and interesting literature has been formulated with reference to visceroptosis from the viewpoint of the biologist, of the internist, of the neurologist, of the orthopedist, and of the surgeon. The workers in each of the special fields of investigation have contributed their respective shares to the sum-total of helpful knowledge concerning the subject, but it may be safely said that to Mr. Lane belongs the credit of tracing the mechanism of the various pathological changes, and of pointing out the most significant and far-reaching results of the condition.

Fig. 1.—Case I. *Inflammatory Stasis.* E. L. Post-operative adhesion of omentum to mesoappendix and stump of appendix. Band across ileum near ileocecal valve, causing constriction when in upright position—ileal stasis.

The phenomena resulting from visceroptosis, as revealed by the investigations of Lane, have been classified by Murray Leslie[4] as follows: "A. The formation of adhesions along the lines of resistance to downward displacement. B. The production of kinks along the course of the gastrointestinal tract. C. Gastrointestinal stasis with delayed digestion, constipation, and autointoxication." The crux, therefore, of the stasis question is a mechanical one, in which the chief factor is the abnormal fixation of any one point in the length of the intestine, with a dropping of the tube on either side of this fixed point, thus producing a kink. The toxic symptoms are secondary to these mechanical changes.

Fig. 2.—Case II. *Evolutionary Stasis.* M. G. Typical Lane's band, with angulation of appendix. Concurrent conditions: Femoral hernia, extrauterine pregnancy, uterine fibroids. Beginning Jackson's membrane.

Lane[5] has traced the mechanism of these changes, and has formulated a theory which is interesting, and apparently reasonable. In early life this ptosis of the abdominal viscera is the result of an abnormal distention of the intestine, consequent upon too frequent feeding, or upon the continued use of an unsuitable diet. In later years, according to Lane's theory, it is brought about or accentuated by the erect posture which man assumes during the waking hours. The point is emphasized that the resulting pressure and strain may produce distinct changes, and that these alterations may take the form of evolutionary bands, which are practically without blood supply, and not to be confounded with inflammatory adhesions, which are apt to have a generous blood supply. These evolutionary bands exist primarily for the advantage of the individual.

Fig. 3.—Case III. *Inflammatory Stasis.* C. H. O. Omental adhesions to cecum, at site of old abscess of appendix, and abdominal wall; intestinal stasis. Traction upon greater curvature of stomach, resulting in fish-hook stomach.

Lane describes the changes which take place as follows:

"1. An abnormal fixation of the pylorus, by the development of a new band, which attaches it to the under surface of the liver, in front of the transverse fissure. The band serves the purpose of affording an additional ligament to the stomach. It may extend forward for a considerable distance in front of the transverse fissure, and may involve the cystic duct and gall-bladder, and interfere with their normal functioning. Again, this band may extend over the pylorus and may attach and help to support the transverse colon.

Fig. 4.—Case IV. *Inflammatory Stasis.* E. V. P. Lipoma of omentum; adhesion of omentum to loop of sigmoid; traction upon sigmoid by omental lipoma, causing distinct kinking; chronic intestinal stasis.

"2. This fixation of the pylorus may result in the production of a kink, which may be sufficient to interfere with the normal functioning of the stomach and duodenum. In consequence of this areas of engorgement of the mucous membrane arise in the front part of the duodenum or in the lesser curvature of the stomach. While the stress sustained at the point of engorgement is a primary factor the lower resistance power to the entry of microorganisms due to autointoxication, takes a large share in the production of the inflammatory changes in the mucous membrane. These areas of abrasion later form ulcers which may after a time become affected by tuberculous, cancerous, or other infections. The ulcer of the duodenum rarely becomes malignant, probably because it so readily yields to treatment. For instance, the performance of a gastroenterostomy will almost certainly result in the healing of a duodenal ulcer, while its curative effect upon a gastric ulcer is often very doubtful. The variation in the locality of the ulcer in the two sexes would appear to be dependent on the difference in the nature of the strain consequent on the varying forms of the abdomen.

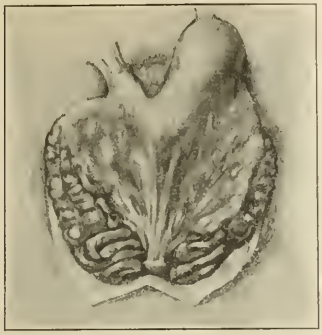

FIG. 5.—CASE V. *Inflammatory Stasis.* J. S. Adhesion of omentum to fundus uteri, making traction upon stomach, causing angulation at pylorus, resulting in marked gastric delay—relative partial pyloric stenosis.

FIG. 6.—CASE VI. *Evolutionary Stasis.* E. O'R. Typical Lane's band, with kinking of terminal ileum; appendix adherent to band. Marked ileal stasis.

"3. There develops on the under surface of the mesentery of the last few inches of the small intestine a new band, which at first forms part of the under surface of the mesentery. Later it forms a ligament distinct from the mesentery. The ligament contracts and deforms the ileum, producing a kink or obstruction of this portion of the intestines, especially in the erect posture of the trunk.

FIG. 7.—CASE VII. *Inflammatory Stasis.* T. M. Band of omentum, two inches wide, firmly adherent to mesoappendix, drawing stomach downward and to right; appendix, throughout its entire length, firmly adherent to cecum.

In consequence of this kink the small intestine becomes very much dilated and this dilatation may extend up as far as the pylorus. The symptoms produced by this obstruction are superficially very much like those of appendicitis and in consequence a large number of normal appendices have been removed to bring about the cure of symptoms resulting from this obstruction, needless to say, without any particular benefit or advantage to the patient. The symptoms produced by this type of obstruction are very definite and need not be mistaken for those which result from a kink in the appendix. This kinking of the appendix is frequently associated with the kinking of the ileum, since they are the result of the same cause, namely, the effort of nature to keep the cecum as much in its place and out of the pelvis as it can.

"4. Strong bands of peritoneal adhesions develop between the outer aspect of the cecum and ascending colon and adjacent abdominal wall with the object of holding up the cecum, which in the erect posture becomes overloaded with fluid contents. These bands may occasionally interfere with the evacuation of the cecum, by producing a kink. One of them not infrequently secures the appendix, which is made to form one of the ties or resistances opposing the downward displacement of the cecum. Unfortunately, the anchoring of the appendix spreads from its base and being hollow the strain upon a portion of the appendix may result in the occlusion of this tube, distal to the point of fixation,

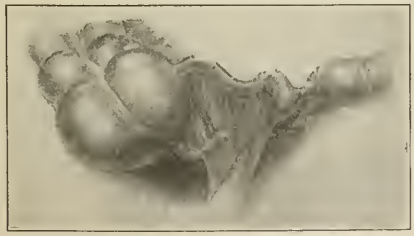

FIG. 8.—CASE VIII. *Evolutionary Stasis.* M. D. Typical broad Lane's band, with adherent appendix, mobile caput coli, and ileal stasis.

and in the formation of an obstruction. I believe that the development of so-called appendicitis is almost always produced in this way. When the appendix is quite free, it is probable that the ileal kink is the cause of the symptoms.

Fig. 9.—Case IX. *Evolutionary Stasis.* V. B. Lane's band; potential kink; Jackson's membrane; ileal stasis.

"5. Both the hepatic and splenic flexures are drawn upwards, reducing the lumen of the bowel at these points and rendering the passage of feces difficult. In consequence, abrasion, ulceration, and cancerous and other infections are common in these situations.

"6. The kinking at these points is much exaggerated by the fall of the transverse colon. The weight of the loaded transverse colon is distributed partly through the ligaments of these kinks and partly through the convexity of the stomach and through the newly developed ligament of the pylorus. When this last ligament extends to and secures the transverse colon, it may occlude its lumen materially at this point, rendering it a favorite locality for cancer. The under surface of the transverse mesocolon shows acquired bands similar to those which kink the end of the ileum.

"7. Nature attempts to keep the sigmoid loop filled with solid feces out of the true pelvis by the formation of bands on the outer surface of the mesosigmoid. These by their contraction convert the mobile loop into a straight fixed tube. The lumen of this tube is subnormal, and its muscular coat is wasted because of its fixation. This fixation of the sigmoid renders the passage of solid feces through it difficult, and this difficulty is manifested as engorgement, abrasion, ulceration, or cancerous or other infection of the mucous membrane. Diverticula or foci of inflammation may develop. These again may become affected by cancer, tubercle, etc. Should the center of this loop escape from the grip of the newly formed bands, the extremities of this loop are approximated by their contraction when the loop itself becomes progressively dilated by the difficulty which arises in its evacuation so that a socalled volvulus results.

"8. The left ovary is frequently involved in the adhesions which bind down the lower portion of the sigmoid and the upper part of the rectum. The ovary becomes cystic in consequence of its fixation in the newly developed bands, later forming a tumor which for a time performs some of the functions so usefully performed by the pregnant uterus of raising the fallen viscera and overcoming obstruction.

"9. The condition of the rectum varies greatly. While in some cases the rectum is short and dilated, in others it is enormously elongated, so that it puddles as a long, loose tube in the true pelvis. This last condition renders the passage of solid feces through it very difficult, since any downward pressure, however great, is exerted at a marked mechanical disadvantage on the fecal contents. . . .

"10. Associated with intestinal stasis, there is a considerable ascent in the level of deleterious organisms in the small intestines with occasional infections of the biliary and pancreatic duct, producing gallstones, pancreatitis, and later cancer of these several structures."

Adhesions or "Evolutionary Bands."—Lane has repeatedly emphasized, and recently reiterated,[6] his contention that the apparent adhesions which result from the strain upon the mesentery and its attachments as a result of the dropping of the viscera are in no sense inflammatory adhesions, but are, on the contrary, merely thickened fibrous bands along the line of stress,—"evolutionary bands," as he chooses to call them. Many of those who accept Lane's theory in general see nothing unreasonable in this idea in particular. Others, however, while agreeing in some features, hold that his views in this regard are not tenable, according to anatomical, physiological, and clinical observation. It is not my purpose here to enter upon a discussion of the various theories concerning the etiology of the adhesive "veils," "webs," and "bands," noted by Lane and others. For those who are especially interested in this particular phase of the subject I append some of the more recent contributions to the literature of intestinal stasis. In a previous communication I gave a brief summary[7] of the literature of Lane's kinks and collateral matter up to May, 1912.

Classification of "Lane's Kinks" with Regard to Point of Occurrence.—Granting, then, the existence of what Lane designates as "evolutionary bands," and accepting the long-established fact that adhesions play a part in the production of varying degress of obstruction to the passage of gastrointestinal contents, we may review, categorically, the points of predilection, as demonstrated by Lane, for the formation of these bands, with the resulting kinks in the gastrointestinal tract:

Fig. 10.—Case X. *Inflammatory, superimposed upon Evolutionary Stasis.* W. S. L. Lane's band, with potential kink; prolapsed transverse colon, ascending colon, and sigmoid; Jonnesco's fold; Jackson's membrane. Three sets of firm fibrous bands, just below ileocecal valve, extend from ileum to right iliac fossa, one to right ovary.

1. Pyloric kinks, due to a band extending from the pyloric end of the stomach to the under surface of the liver, with angulation in the first portion of the duodenum.

2. Duodenal or duonedojejunal kinks, in the third part of the duodenum, at the commencement of the jejunum, due to the pull of an overloaded ileum, obstructed by an "ileal kink" at its termination.

Fig. 11.—See legend under Fig. 13.

3. Ileal kinks, at different points along the terminal coil of the ileum, usually with downward displacement and rotation inwards of the cecum, the result of nature's efforts to overcome the effects of the strain caused by the ptosis of the organs.

4. Kink of the appendix, due to bands in the ileocecal region; or the appendix may be thickened and so attached as to form a suspensory ligament, when the patient is in the erect position, causing stasis of the ileum.

5. Kink of the hepatic flexure and first part of the transverse colon, usually due to the attachments of the gut to the kidney, to abdominal wall, or to the attachment, one to the other, of the two kinks of the flexure.

6. Kink of the splenic flexure, due to the strong costocolic ligament which holds this portion of the gut in place, despite the dropping of other parts,

Fig. 12.—See legend under Fig. 13.

thus causing angulation when the transverse colon is ptotic.

7. Sigmoid kink, due to evolutionary adhesions fixing the sigmoid as it crosses the brim of the pelvis on the left side.

8. Kink of the rectum, not really a kink, but acting as one, in consequence of elongation of this part of the tube through fixation of the upper portion of the sigmoid loop, while the remainder becomes free, joins the rectum, and thus forms a long, loose pipe, which occupies the true pelvis, affording a marked obstacle to the passage of feces.*

Stasis.—The natural outcome of this kinking of any portion of the drainage tube is obstruction to the lumen of the intestine at the point of the kink, with "puddling" in the dependent portions, damming back and infection of the contents, and general slowing of the drainage of the canal. To this state of affairs Lane[8] has applied the term "chronic intestinal stasis," which he defines as follows: "Such an abnormal delay in the passage of the intestinal contents through a portion or portions of the gastrointestinal tract as results in the absorption into the circulation of a greater quantity of toxic or poisonous materials than can be treated effectually by the organs whose function it is to convert them into products as innocuous as possible to the tissues of the body." This reabsorption and autointoxication, in Lane's opinion, lead to a general lowering of the resistance of the body and to the concomitant increase in susceptibility to various diseases.

Symptomatology.—The symptomatology of advanced stasis due to kinks of the intestine has been so admirably stated by Chapple[9] that I give it here as formulated by him. He reviewed fifty cases, in which he found the following constant set of symptoms: "(1) Headaches, which were severe and frequent. (2) Attacks of nausea, often followed by retching or actual vomiting. In some cases the vomiting was very frequent indeed and of a severe nature. It was very interesting to note that in several of the cases blood was frequently present in the vomit, and had led very able men to the diagnosis of gastric ulcer, although none such was found at the operation. (3) Loss of appetite was almost constantly present. (4) Loss of weight was present in all cases. (5) Markedly cold hands and feet, which gave an indication of a defective

Fig. 13.—Case XI. *Evolutionary Stasis.* H. B. Ulcer of stomarch; dilatation of duodenum; mobile cecum; Lane's band and kink; Jackson's membrane; duodenojejunal kink; adhesions between ovary, tube, and sigmoid

*It may be noted that when the patient is in the erect position these fixed points in the intestine are above, or toward the upper part of the abdomen, while the sagging portions of the gut on either side are below. When the subject is lying down the exact reverse of this is true. When the patient is in the prone position there is a "potential kink"; when in the erect position, there is an "actual kink." This doubtless explains why, at operation, some surgeons are unable "to see the kinks."

circulation. (6) Mental apathy. This was very definite in most cases. It was most marked in case XXX, who was in a state that was well described by her medical attendants as one of torpor. Many felt that death would be a welcome relief from

Fig. 14.—Case XII. *Inflammatory and Evolutionary Stasis.* N. R. Mobile caput coli, with twist of ascending colon just below ileocecal valve. Typical Lane's band; ileal stasis.

their physical and mental misery, and two had actually attempted to bring about that end. (7) Constipation, which in all was persistent and its previous treatment had failed. One case had gone on several occasions for twenty-eight days without an action of her bowels in spite of treatment. (8) A constant foul taste in the mouth, which was often accompanied by foul breath and carious teeth. The tongue was constantly furred. (9) Attacks of abdominal distention, which were accompanied by discomfort and relieved by eructation or the passage of flatus or an action of the bowels. (10) General muscular pain and a loss of freedom in the movement of the joints."

Physical examination, in Chapple's experience,

Fig. 15.—Case XIII. *Evolutionary Stasis.* H. M. Mobile cecum; adhesion between Lane's band and cecum; adhesion between band and broad and infundibulopelvic ligaments. Ileal stasis.

which is corroborative of that of Lane and others who have studied stasis cases, revealed: (1) Skin staining, as a rule of a sallow brownish nature, associated with more definite localized patches, especially under the eyes, in the axillæ, and in the groins. (2) Breast changes, simulating, in the early stages, chronic mastitis, and in the later stages cystic degeneration. (3) Abdominal tenderness over the areas of fixation.

Classification of Cases of Intestinal Stasis into

Fig. 16.—Case XIV. *Inflammatory Stasis.* W. C. B. Adhesion between ascending mesocolon and abdominal wall. Marked ileal stasis, amounting almost to obstruction. Patulous ileocecal valve.

Clinical Groups, According to Predominant Symptoms.—As the study of chronic intestinal stasis has proceeded, the cases have been classified according to the predominant symptoms. In a recent contribution Schlesinger,[10] who, as Mr. Lane's house-surgeon, Guy's Hospital, London, has had an ample opportunity of studying the cases before, during, and after operation, has classified them under the following types:

(1) Obstructive, usually regarded as having duodenal ulcer, a gastric growth, or what is known as "nervous dyspepsia." Patients of this class, usually males, complain of pain after taking food, immediately or after an interval, with relief after vomiting. Headache, cold hands and feet, pigmentation, and the usual "toxic" symptoms are present in varying degress. Such patients, according to Schlesinger, usually have thickened or spasmodic arteries, with consequent increase of blood pressure. The abdominal muscles are well developed. The point of pain, upon examination, to

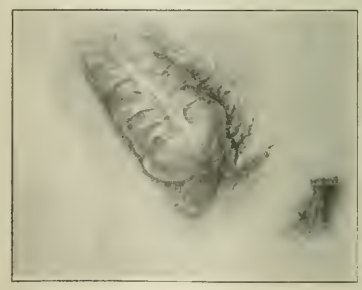

Fig. 17.—Case XV. *Evolutionary Stasis.* J. F. Typical Lane's band and kink; ileal stasis.

which such patients direct attention is over the duodenum. Tenderness to pressure in the iliac fossa. *x*-ray examination reveals a firmly fixed point in the ileum, and a dilated and hyperthrophied duodenum. He claims the patients are invariably completely cured by ileocolostomy.

(2) Toxic or suprarenal type, more generally found in women, is the type most commonly recognized. Constipation is generally present and often extreme. The group of symptoms diagnosticated as "toxic" overshadow the direct abdominal symptoms. These toxic symptoms are both subjective and objective. Mental depression, sometimes of a very marked degree, is the chief symptom. The pigmentation is marked in these cases, there are low blood pressure, cold and clammy hands and feet, and general asthenia, suggestive of Addison's disease. Vomiting or severe retching is a fairly constant symptom. Profuse perspiration, of a disagreeable odor, headache, harsh and inelastic skin, cystic degeneration of the breast, and extensive pyorrhea alveolaris, are other symptoms noted by Schlesinger in this type of patients. Abdominal pain may not be complained of, but tenderness over the ileum and the sigmoid is elicited upon examination. The ovaries are often considered the source of trouble in these cases, and single or double oöphorectomy is not infrequently performed. "This is the extreme picture of this type of case," according to Schlesinger, "but all stages of the condition, from the patient who has occasional 'bilious attacks,' through the various types of so-called indigestion, atonic constipation, neurosis, etc., can be recognized."

FIG. 18.—CASE XVI. *Evolutionary Stasis.* M. D. Angulation of appendix by ileal band; ileal kink; ileal stasis.

FIG. 19.—CASE XVII. *Inflammatory Superimposed upon Evolutionary Stasis.* S. F. Lane's band; ileal kink. Adhesion between ascending and transverse colon.

(3) Mixed type, including those patients who present a mixture of the symptoms of the "obstructive" type with those of the "toxic" type.

(4) End-result type, comprising a large group of cases (*e.g.*, intestinal cancer, gallstones, tuberculosis, rheumatoid arthritis, Still's disease, etc.), in which the end-result overshadows the underlying cause. This last group of cases, comprising, as it does, many of the conditions which have formerly been generally considered, and which are still considered by some, as the causative factor in the production of intestinal obstruction, brings us back to the "first horn of the dilemma" of interference with the flow of the contents of the drainage canal.

Diagnosis.—The diagnosis of "static" cases seems to have become, with Mr. Lane and his associates, almost a matter of that "imponderabilia" which amounts, practically, to what we call intuition. The symptom-complex is so well defined, once it is fully recognized and verified by repeated laparotomy, that the cases can be recognized almost at a glance. It is not to be inferred from this, however, that Mr. Lane or anyone else, no matter how skilful in diagnosis and expert in surgical technique, attempts to justify operating solely upon this snapshot picture. No patient should be subjected to laparotomy for the correction of presumptive kinks and chronic stasis until a careful physical examination has been reinforced by an equally careful radiographic study of the case. The *x*-ray readings must be checked up with the clinical findings, for it must be borne in mind that many twists and turns of intestine may be found which produce very little stasis.

The degree of obstruction, as well as the location of the obstructing kink, has been carefully studied by Mr. Lane, with the aid of the excellent radiographic work of Dr. Alfred C. Jordan, Medical Radiographer to Guy's Hospital.[11] The radiographic study of my cases has been made by means of a bismuth meal, from 4 to 6 ounces, of the subcarbonate of bismuth being given in milk, or with bread and milk, six hours before the first picture is taken. Pictures are then taken every hour for from six to twelve hours after the bismuth meal, one 24 hours thereafter, and then, according to the circumstances of the individual case. If, at the twenty-four-hour exposure, the results are not satisfactory, an injection of bismuth by rectum, with an immediate exposure, will sometimes demonstrate a kink which has not been shown by the other method. By using the screen and palpating the abdomen over the area being studied, the fixed point or points can sometimes be demonstrated more clearly than by any other procedure. The rapidity of the passage of the bismuth through the canal has been found to vary widely. Jordan has called attention to the fact that the contents of the ileum pass along at a rate approaching two inches a minute, and that the bismuth meal begins to pass through the ileocecal valve within four hours. With an ordinary two-ounce meal, the entire quantity of bismuth is in the cecum and ascending colon at the end of six hours, in the average normal case. With a five or six ounce dose, some bismuth will be found in the lower end of the ileum after five, six, or eight hours in normal persons, according to Jordan's studies. He advocates, therefore, the five and six ounce doses, from which he has found no ill effects. It is important, of course to use a pure preparation of bismuth.

Classification of Cases from the Point of View of Treatment.—Having considered the cases of intestinal stasis with reference to the point of kinking, and with reference to the dominant features in the symptom-complex, we come now to the classification of cases with reference to treatment. For purposes of convenience the cases may be considered under the following types:

(1) Atonic or asthenic, in which there is general loss of muscular tone and nervous energy, with a slight degree of ptosis of the hollow viscera. In this class of cases there is usually a dropping over the brim of the pelvis of a loop of the ileum, causing increased resistance to the intestinal contents, or the duodenojejunal junction may be pulled upon and angulated. These are the milder forms of stasis, which may be easily corrected by abdominal supports, by tonic régime, by building up the nutrition, and by rest, until the tonus of muscles and nerves has returned.

In the treatment of this class of cases liquid paraffin has been found particularly useful. Mr. Lane,[12] in calling attention to this agent in the treatment of intestinal stasis, says: "It is a curious thing that while paraffin has only very recently been employed for this purpose by the medical man, it has been in use for time immemorial among miners and savage races for the treatment of almost any known disorder. Just how paraffin acts is not perfectly clear. In animals it destroys the worms that infest the intestinal tract, and such parasites as live on their skin. The eggs of *Ascaris lumbricoides*, which will go on dividing in glacial acetic acid, when placed in paraffin die, and no division takes place; and skin mycosis in a large bird, which resisted treatment with iodine, has been cured by daily applications of paraffin forcibly rubbed in. It also cures the dysenteric conditions to which animals are so liable, especially in captivity. Yet paraffin is apparently perfectly innocuous to the human subject, and loses none of its bulk in its passage through the intestinal tract." Liquid paraffin (oleum mineralis Russicum), is not mentioned in the National Standard Dispensatory (U. S. A.), edition of 1909.* In the British Pharmacopeia, last edition, it is described as a colorless, thick, oily liquid, practically tasteless and odorless. Finnemore[13] calls attention to the fact that there are two varieties of liquid paraffin on the market at the present time, in addition to the pharmacopeal one. "It is prescribed," he says, "in the pure form in doses of half to one fluid ounce two or three times a day. The smaller quantity once a day is often sufficient for patients not confined to bed. Although it has practically no taste, and most patients do not object to it, yet it is not pleasant to swallow this large amount of thick, oily liquid, and it is improved by flavoring with one minim to each ounce of one of the volatile oils, such as bitter almond, anise, cinnamon, cloves, lemon, or peppermint. For those patients who find it unpleasant to take on account of its oily nature, it is a good plan to prescribe it in the form of an emulsion, which appears to the writer to have the very decided advantage, that although it is as thick as the paraffin it can be diluted with water before taking to make a thin preparation which can be taken without the slightest discomfort."

(2) Misplaced appendix. Sometimes in connection with the condition known as "cecum mobile," described by Houssmann, in 1904, by Wilms, in 1908, and referred to in connection with intestinal stasis by Coffey and others, there may be displacement and kinking of the appendix, which acts as a ligament, twisting the mobile cecum or pulling it downwards, and with it the ileocecal valve. In some instances the ileum is drawn downward below the cecum, causing a kink above. In cases where the appendix is only slightly misplaced, and the consequent kinking is of a minor degree, removal of the appendix and correction of the kink will relieve the resulting stasis. Before the subject of intestinal stasis was cleared up by Lane, cases of this class, which are accompanied by symptoms of appendicitis, were considered as appendicitis cases, and were operated upon accordingly. The appendix was found to be only slightly diseased but its results were successful out of all proportion to the lesion. In the severer types of this class of cases, disappointment followed removal of the appendix. Mayo,[14] in calling attention to these cases, says, "For a number of years past, in dealing with intestinal stasis believed to be due to a diseased condition of the appendix, in which the seriousness yet obscurity of the symptoms required a larger incision for exploration than was usually made for the removal of the appendix when it was unmistakably diseased, and the symptoms more definite, we have at times noted a definite kink of the ileum within three inches of the ileocecal valve. However, the frequency with which the condition was seen in certain cases did not occur to us until a few years ago, when our attention was personally called to it by Arbuthnot Lane." Coffey[15] reports having called in a number of his previously operated appendix cases and having cured them by cutting the evolutionary band which formed with the dropping down of the ileum, and placing purse-string sutures in the upper leaf of the mesentery of the ileum, thus shortening it by plication.

(3) Ileal kink, from evolutionary bands about the ileum—"crystallization of lines of strain," as Lane calls them. These kinks may occur at different points along the terminal coil of the ileum, and may be due to the development of bands along the line of the strain induced by visceroptosis, independently of misplacement or kinking of the appendix, described under (2). The milder degrees of ileal kink may be corrected by simply cutting the adhesive bands, taking care to cut one way and sew up another, in such way as to lengthen. In the form with broad bands, however, it may be necessary to divide the ileum, inserting it directly into the pelvic colon or rectum obliquely by an end-to-side anastomosis (ileocolostomy or ileoproctostomy). After the anastomosis has been made, a running suture is placed in the peritoneum intervening between the large and small bowel, and the space obliterated. Broad bands, when cut, leave raw surfaces which, if not covered, invite the formation of adhesions. These raw surfaces may be covered with peritoneum, as indicated, or by a piece of omentum. I am now testing the efficacy of the latter method. A piece of omentum is detached and split, the raw surface being covered over with one layer.

(4) Kinking of duodenojejunal junction, usually secondary to ileal stasis. Evolutionary bands in this region may cause marked kinking, with secondary effects in the duodenum, the first part of which becomes distended. The second and third parts,

*Efforts are being made to secure a pure and refined paraffin in this country. This should be demanded, as druggists are prone to substitute another preparation.

which are under the peritoneum, are not much affected. Adhesions may form about the pylorus, giving rise to obstruction, which may lead to the mistake of interpreting the *x*-ray findings, reading into them "cancer of the pylorus," with the prognostication of impending death for the patient. The kink at the duodenojejunal junction can be corrected by cutting one way and sewing the other, or the loop of jejunum may be placed in the position of gastroenterostomy, held by several stitches of silk or linen. A gentle curve is thus made and the sharp angle obliterated. In some of these cases it may be necessary to resort to ileocolostomy, as described by Lane. Raw surfaces are always to be turned in to prevent the formation of inflammatory adhesions.

(5) Changes at the hepatic and splenic flexures of the colon, often with the formation of adhesions. In mild cases, with prolapse of the colon, Coffey's[16] omentopexy operation may be employed. In the presence of more marked adhesions, with disease of the transverse colon, the question of colectomy may be considered. Other attempts at correction may be made before this radical procedure is employed. Kinking at the hepatic and splenic flexures, it may be said in passing, transforms these round turns into sharp angles, subjecting these areas to increased irritation, and rendering more liable the production here of malignant disease.

(6) Changes at the sigmoid loop.* Sometimes the ends of the loop are brought together by the evolutionary bands. These bands may extend from the peritoneum external to the mesosigmoid, shortening it up, until, as Lane has pointed out, the mobile loop of bowel is replaced by a short, straight tube, which crosses the iliac fossa obliquely, with only a partial peritoneal covering. Lane calls attention to the observation that this type of change exists apparently without exception in tuberculous subjects. In some of these individuals the portion of mobile gut which intervenes between the upper fixed portion of the sigmoid loop and the portion of the rectum which has no peritoneal covering, is exceedingly long. This fact renders it possible to insert the ileum into the mobile loop, close to its termination. "Never put the ileum into the large bowel above the level of the brim of the true pelvis," cautions Lane, "since the communication is then affected above the last kink, or obstruction, which, curiously, is one of the earliest to develop." Anastomosis should be between the ileum and the beginning of the pelvic colon.

(7) Extreme cases, with diverticulitis, many bands, and much persistent pain. Exsection of the large bowel is indicated.

(8) Various kinds of adhesions of an inflammatory and noninflammatory nature. Remove the adhesions and cover over the raw surfaces.

Treatment. Preparation for Operation.—Preparation for the radical treatment of chronic intestinal stasis is instituted 48 hours before the time of operation. An ounce or two of castor oil is given eight or ten hours before operation. Three or four enemas are given, Mr. Lane, as a rule, using treacle for the purpose, others preferring the ordinary soap enema. Nothing is administered by mouth except beef tea and brandy and water. Saline hypodermoclysis into the axillæ is begun with the anesthetic and continued throughout the operation. One quart to three pints of saline solution under each breast, in prolonged operations, sustains the patient, keeps up the blood pressure, and prevents shock. Sterile glucose or dextrose, one-half ounce to the pint of physiological saline solution may be injected under each breast.

Surgical Technique.—For the benefit of those who happen not to be familiar with the technique of the more important operative procedures concerned in the correction of intestinal kinks and the eradication of chronic intestinal stasis, the technique of the two operations advocated by Lane is given: (1) Ileocolostomy (Lane's "shortcircuiting" operation). (2) Colectomy.

Anesthesia.—It is particularly important in these cases that perfect muscular relaxation be maintained throughout, that absolute quiet on the part of the patient be insured, and that postoperative vomiting be avoided. For these reasons, I prefer to operate under the essence of orange-ether sequence, as originated and practised so successfully by Gwathmey. As a routine practice, I dilate the sphincter ani after the operation, thus insuring freer escape of gas and other intestinal contents.

Ileocolostomy.—The abdomen is opened through the left rectus, or in the median line. The viscera are subjected to careful examination, in order to determine the location and degree of obstruction. The lowest point of obstruction is located. The ileum is divided slightly obliquely, encroaching upon the convexity; the distal end is invaginated by a purse-string suture, and the proximal end is implanted into the lowest accessible portion of the ileopelvic colon. Above this point the sigmoid is kinked. When this step of the operation is completed, a full-sized esophageal tube is introduced through the anus, up through this anastomotic juncture. It is fixed in position by a suture through the perineum. In passing the tube beyond the junction any difficulty which may be encountered is obviated by using a Higginson enema syringe, one end of which is attached to the tube, while the other is placed in a bowl of liquid paraffin. By a few squeezes of the syringe bulb, a small amount is forced up into the bowel. The tube is thus easily passed beyond the junction.

Colectomy.—If the symptoms are of sufficient severity or chronicity, or if they are recurrent after the performance of ileocolostomy, it becomes necessary to resort to the more radical procedure of resection of the colon up to the point of anastomosis of the ileum with the colon. The mesocolon is ligated and divided. The ileum is divided near the cecum and the end toward the large intestine—the distal end—is invaginated; the proximal end is implanted into the pelvic colon by a slightly oblique anastomosis.

After-treatment.—If the tube does not drain properly at the end of twelve hours, six or eight ounces of liquid paraffin may be passed in. For the first twelve hours brandy and water, or champagne, may be given, and the usual diet gradually instituted. Morphine may be exhibited freely after the operation if there is much pain. An ounce of liquid paraffin is administered, by mouth, three times a day, as long as may be necessary. The patient is placed in the Fowler position for several days and then let down gradually. The stitches holding the tube in place are cut on the fifth day, and the tube is removed on the sixth day. The tube usually

*It may be noted that in the newer British textbooks on anatomy the term "sigmoid" is not employed, the portions of the colon being designated as "descending," "iliac," "pelvic," colon, and rectum.

drains between twelve and twenty-nine ounces in the twenty-four hours. It should be borne in mind that, in these cases, a tendency to infection in the wound may be noted about the tenth day after operation. This is not due to external infection, but to the action of the colon bacillus, which, it has been shown, can burrow its way through the intestinal wall, without an opening.

In several cases in which gastroenterostomy was performed for pyloric obstruction secondary to intestinal stasis, a pure growth of *Bacillus coli communis* was cultivated from the contents of the stomach and duodenum, thus showing the existence of an ascending infection in these cases. In this connection it is interesting to note that examination, made by Dr. J. W. H. Eyre, of London (observations not yet published), of the bodies of forty patients, dead of accident, showed the duodenum to be sterile.

Prognosis.—The prognosis must be modified, of necessity, in accordance with the conditions found in the individual case. In the vast majority of the milder forms of kinking and stasis, in whatever portion of the gastrointestinal tract, the simpler surgical procedures will prove effectual. In many of these types the non-surgical measures to which reference has already been made, will restore the normal relations of the abdominal viscera, allowing the unimpeded onward passage of the gastrointestinal contents, and thus relieving the stasis and its concomitant symptoms. When the more radical measures are indicated, the prognosis must be considered from the point of view (1) of the operation itself, and (2) of the relief of the condition to be remedied. Chapple and Mullins collected the histories of sixteen operations at Guy's Hospital between June, 1909, and June, 1910, with one death. This was due to the bursting of an abscess from the abdominal wall into the peritoneum seven days after the operation. With reference to the results, Chapple [9] makes the following statement: "I do not wish to convey the impression that all these patients have been restored to a condition of perfect health. In a large number this has been done. This list includes many of the earliest cases, and this brilliant piece of work has been carried out on material that might well be described as wreckage. Even a casual glance at the patients and their stories shows the nature of the conditions that had been dealt with, and we must not forget that all other treatment had hopelessly failed. Speaking generally, I take it that the object of any surgical procedure is to render the individual more efficient, and to what extent success has been attained in these cases must be obvious to all. One has only to see these patients to realize how good the results really are."

Cases.

In the vast majority of instances, unless there is a congenital defect, the conditions described are preventable and should not be allowed to progress to the degree which calls for operative interference. A more intelligent understanding of the importance of exercise, of proper hygienic régime, of position, and of adequate support to the abdominal organs, will do much toward obviating the lodging of large quantities of material at given points in the intestinal canal. With this accomplished, chronic intestinal stasis will be forestalled. It is for this reason that Mr. Lane's brilliant pioneer work deserves the most widespread and careful consideration.

Whatever may be their cause, the conditions described by Mr. Lane do exist, as I have been able to demonstrate in a large number of cases. The accompanying pictures, reproduced from drawings made at the operating table, with brief historical data of the actual conditions found, are selected from the number merely for the purpose of demonstrating various types of adhesions, "evolutionary bands," and membranes, found upon examination of the abdominal contents by laparotomy. No attempt is made to give detailed histories of the cases, to outline the surgical procedure, or to trace the results. It may be said, however, that in all cases in which the length of time has been sufficient to warrant an opinion, the symptoms, as a rule, have been relieved; in some, absolute cure has resulted. At a later date I shall present a large series of cases, with accurately collated data concerning each.

EXOPHTHALMIC GOITER CURED BY LIGATING ONE SUPERIOR THYROID ARTERY

By LEIGH F. WATSON, M.D.,

OKLAHOMA CITY.

THE simple and conservative operations are steadily gaining favor in the treatment of goiter because of their safety and ease of application. A single or double ligation always benefits even though it does not cure every case.

FIG. 1.—Showing the enlargement of the right thyroid gland. The left side is only slightly enlarged

FIG. 2.—The local anesthesia infiltration is about two inches in length along the inner border of the sternomastoid, with its center at the upper border of the thyroid cartilage.

FIG. 3.—The superior thyroid artery is transfixed at the upper pole with a mass ligature, as advocated by Crile. He believes it is more important to cut off the nervous communication with the brain than to shut off the blood supply to the gland. The wound is closed with a subcuticular suture of plain catgut. The exophthalmos is well shown in this picture.

Operations on the thyroid should be performed under local anesthesia whenever possible. The advantage of local anesthesia lies in the nerve block which completely isolates the brain from the field of operation. This prevents the shock and exhaustion of the brain cells, as first shown by Crile, which is largely responsible for the severe and often unexplainable reaction that frequently follows thyroid operations. Ligation should be preceded by several days' rest in bed while the operator gains the confidence of the patient. This eliminates much of the

FIG. 4.—Taken two weeks after the ligation. There is a noticeable recession of the exophthalmos, although the gland is still enlarged.

FIG. 5.—Taken six months after the ligation. There is only a slight exophthalmos. The thyroid enlargement has entirely disappeared.

shock due to fear. One hour before operation the patient receives a dose of morphine or morphine and hyoscine, sufficient to allay restlessness and prevent psychic shock.

CASE REPORTS.—Mr. J. M., age thirty, married, clerk. For the past three years he has been subject to frequent psychic storms; during these attacks the right thyroid gland increased two to three times its normal size, and the pulse mounted to 150-160 and the temperature rose to 103°-104° F. The pulse for the twelve months preceding ligation had never been below 130. The exophthalmos was steadily increasing. Oct. 1, 1912, the pulse was 135 and temperature 99° F. The enlargement was practically all on the right side, therefore only the right superior thyroid was ligated at this time. Ligation was done in the patient's home under local anesthesia.

The following day the temperature was normal and pulse 90; the latter has steadily become slower until now, ten months after the ligation, it ranges between 70 and 75. The patient says it is slower than ever before. He was back at his place in a grocery store two weeks after the ligation and has not missed a day from work since then. He received ergotin, gr. 1, with quinine hydrobromate, gr. 2, and thyroidectin, gr. 3, three times daily. He took this for two months. He then noticed that there were intervals of several days without the pulse rate increasing on exertion. During the third month he took the medicine about half the time, then stopped it entirely as all symptoms had disappeared.

The immediate improvement must be credited to the ligation. He received the same medical treatment for three weeks preceding the operation; it was without effect on the insomnia, nervousness, exophthalmos, tachycardia or psychic storms.

Two weeks after ligation both thyroids began to enlarge symmetrically. This gradually increased for six weeks, and for a short time the patient was unable to wear a collar; but the nervousness, insomnia, and psychic storms had disappeared and the tachycardia and exophthalmos were rapidly improving. In the third month the enlargement began to subside and within three weeks had entirely disappeared and the gland assumed its normal size.

A COLLAPSIBLE-WEIGHTED STOMACH-TUBE AND A NEW GASTRIC GLASS BULB.*

By I. O. PALEFSKI, M.D.,

NEW YORK.

The passage of a stomach-tube is by no means a pleasant experience and the difficulties encountered in lavage and extraction of test-meals are familiar to every practising physician. In this communication I shall point out the causes responsible for such difficulties and will describe a modified stomach-tube devised by me, free from any of these.

The disadvantages which the present stomach-tube possesses arise from two sources. First, its tubing is thick and firm—practically non-collapsible. Secondly, its passage through the oral-esophageal

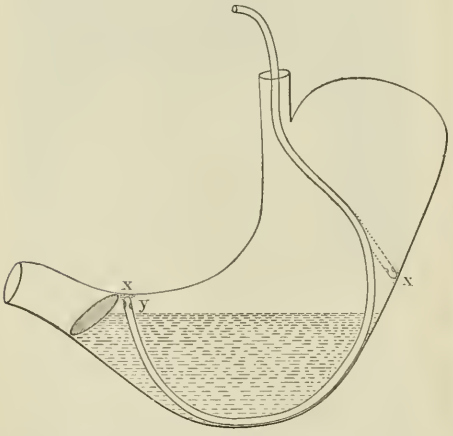

Fig. 1—The introduction of the ordinary stomach-tube. X and X' show the tip striking the greater and lesser curvatures respectively.

tract is a forcible one, at times even a violent one. By referring to Fig. 1 it will be observed how the tube first strikes the floor of the stomach, then follows for some distance the greater curvature and emerging from the under surface of the gastric contents, strikes and irritates at the lesser curvature. The adjustment of its eyes to the level of the gastric contents necessitates the constant moving of

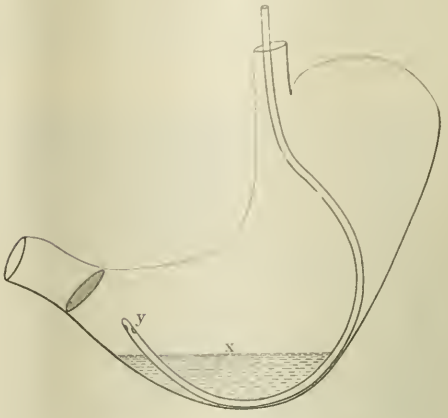

Fig. 2—Incomplete evacuation of the stomach. X—level of the gastric contents. Y—the eyes of the tube above this level.

the tube back and forth giving rise to gagging, coughing, vomiting, and sometimes even traumatism. Furthermore, with this tube the stomach can be seldom completely evacuated owing to the fact that the long axis of the tube is thrown into a curve and its eyes are at a higher plane than the most dependent portion of the stomach (Fig. 2). A moderate degree of gastric stasis is very often undetected. Finally, as the passage of the tube is apt to cause exhaustion, its use is contraindicated, or to be exercised with a great deal of care, in the old and debilitated, in gastric and pyloric ulcers, and in advanced cardiac or pulmonary diseases.

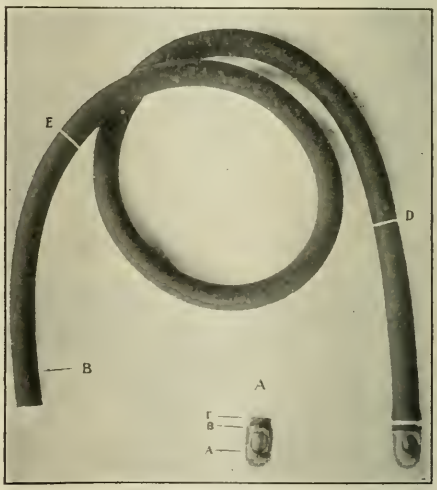

Fig. 3—Palefski's Modified Stomach-tube. (G. Tiemann & Co., N. Y.) A—Gold plated lead tip; a, solid half; b, hollow and perforated half; c, neck. B—Soft and collapsible tubing; d, 15 cm. mark.

*From the Gastroenterological service of the Montefiore Home and Hospital. Demonstrated before the Harlem Medical Association, February 5, 1913, and before the Section on Medicine, New York Academy of Medicine, April 15, 1913.

The passage of the modified stomach-tube depends upon the force of gravity assisted by deglutition but is uninfluenced by the force of the introducing fingers. It consists of: (Fig. 3) A. A gold plated lead tip weighing 140 grains, ¾-inch long, and 25 French, one-half of which is solid serving

Fig. 4—Introduction of the modified stomach-tube (stage 2), showing the position of the patient and the operator supporting the outer end of the tube, which is moving down the esophagus by gravity.

as a weight and the other half hollow and perforated, terminating in a neck to which is attached by means of silk, thread No. 1. B. Soft and collapsible pure gum red tubing, 60 centimeters long, 25 French, and 6 by 8 millimeters in diameter. It is marked off at 15 and 45 centimeters from the metallic tip, showing when the latter has reached beyond the pharynx and cardia respectively. The diameters of the lumen of the tube of the eyes and of the neck of the metallic tip are of equal size, thus allowing the free passage of the gastric contents.

Procedure: This may be described as consisting of three stages: Stage 1, during which the tube pases through the mouth and pharynx. The patient in the recumbent posture rests and extends the head over a pillow with the mouth wide open. The operator places the metallic tip on the dorsum of the tongue or directly into the pharynx and tells the patient to swallow it, after which the latter assumes the erect posture. Sometimes, and particularly the first time, the patient refuses to swallow the metallic tip, in which even I make use of a flexible stylet consisting of a double length No. 8 French catheter of gum elastic. When introduced into the stomach-tube, the latter is made temporarily more resilient, allowing the operator to introduce the metallic tip beyond the pharynx and thus obviating the necessity of having it swallowed by the patient. However, the stylet must be removed as soon as mark 15 centimeters has approached the lips while the patient is still in the recumbent posture. The use of the stylet is seldom necessary after the first or second time on the same patient, as the latter readily learns to swallow the metallic tip without much discomfort.

Stage 2: The patient having assumed the erect posture with open mouth breathes deeply and slowly. The operator, supporting the outer end, allows the weighted tube to move into the esophagus by gravity until mark 40 centimeters has approached the lips. The length of time required for the passage of the modified stomach-tube becomes an unimportant factor owing to the fact that by its use the irritation and discomfort have been minimized. The more slowly this stage is performed the more readily the tube reaches the cardia. There is also a tendency on the part of the patient to chew the tube, which action invariably hinders its passage. The patient, therefore, must be instructed to keep his lips apart (Fig. 4).

Stage 3: When the tube has reached the cardia, as evidenced by the mark 40 centimeters near the lips, the patient places himself on the right side, the right cheek resting on the pillow, the mouth open (Fig. 7), and the head brought slightly forward. In this posture the pylorus (Fig. 5) is the most dependent part of the stomach and gravity will cause the weighted tube to move along the lesser curvature toward the pylorus where also the gastric contents have collected, while the tube will be seen moving into the mouth 10 to 15 centimeters more. Its eyes are constantly under the level of the gastric contents, and hence the stomach now can be completely evacuated—a remote possibility with the ordinary stomach-tube.* In extraction of test-meals an aspirating bottle and suction bulb will remove the gastric contents. In lavage the patient lies first on the back then on the left and finally on the right side. The entire gastric mucosa is thus thoroughly washed of its mucus. To make it suitable for lavage the tube must be lengthened, after its introduction, by another length of tubing connected by means of a glass connecting tube. In its removal it is slowly withdrawn until it stops at the pharynx. The patient is told to swallow, after which the metallic tip appears in the mouth.

Advantages of the modified stomach-tube: (1) Its tubing has no resistance, hence, it does not irritate the gastric mucosa. Blood in the gastric contents, if present, will, therefore, point to some organic condition. (2) By its use a moderate degree of gastric stasis will be readily detected. (3) It

*This was found true by giving patients to eat on a fasting stomach three slices of bread and one glass of water, removed at once, measured, and followed by a stomach wash—the water returning clear. The quantity recovered equaled that ingested within the limits of 5 to 15 cubic centimeters.

may be kept in the stomach as long as desired. (4) It lessens preparation and renders assistance unnecessary in lavage and in the extraction of test-meals. (5) As its introduction causes no exhaustion, it may be employed in conditions in which the use of the ordinary stomach-tube is contraindicated. (6) In

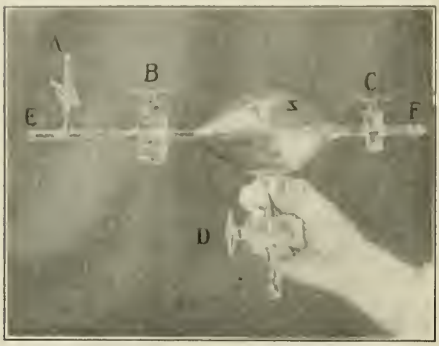

Fig. 6—Palefski's Gastric Glasss-bulb. (Eimer & Amend, N. Y.) A—Inlet for air. B—Inlet for gastrict contents. C—Outlet for air. D—Outlet for gastric contents. E—Gastric end. F—Suction end.

inflation of the stomach, effervescent powders generally are employed, which, invariably, produce overdistention and distortion, besides giving rise to epigastric distress. Following lavage or extraction of test-meals, an inflating bulb attached to the outer end of the tube will inflate the stomach to any desirable degree without any distress whatsoever. (7) Finally, it enables one to study the functions and disturbances of the stomach more readily and more accurately.

Contraindications of the modified stomach-tube: (1) In emergencies requiring rapid action. (2) Whenever the cooperation of the patient cannot be secured, as in a state of unconsciousness, etc.

I have used the modified stomach-tube for the last year and a half on hundreds of patients at various stages of life with surprisingly good results. It must be remembered, and I cannot too strongly emphasize that its successful use depends upon the correct knowledge of the technique employed in its introduction into the stomach, which, I am certain, will be acquired with little practice on those into

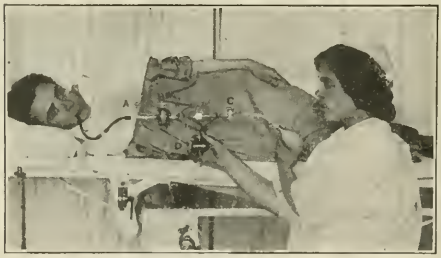

Fig. 7—Aspiration of gastric contents: A and D closed; B and C open; E attached to the stomach-tube.

whom a stomach-tube had been passed once or twice, and this must be learned even by those who have been passing stomach-tubes quite frequently. With it lavage and extraction of test-meals are performed with more thoroughness and with less distress and discomfort and the patients submit themselves more readily for subsequent examinations and treatment.

A New Gastric Glass Bulb.—The purpose of this device is to facilitate the aspiration and collection of gastric contents. It is a graduated ten ounce glass bulb having two inlets, A and B, and two outlets C and D (Fig. 6) for air and gastric contents respectively, each opened or closed with stop-cocks. It is attached to the outer end of the stomach-tube after its introduction and a suction bulb at C will now aspirate the gastric contents into the glass bulb provided A and D are closed and B and C are left open. When filled to its capacity the gastric contents in the glass bulb can be emptied through D into a receiving vessel. It can be used with low and high suction power. In the former case the cock B is left unclosed during the manipulation with the suction bulb at C. With each suction about ten to fifteen cubic centimeters of gastric contents are aspirated into the glass bulb. In the high suction method A, B, and D are closed and the air in the glass bulb is rarified through C with the suction bulb or mouth, using a clean mouthpiece. On opening B, the gastric contents then will flow into the glass bulb three or four ounces at a time. The cock A comes into play in this method when the tube occasionally collapses, due to obstruction by large particles of food, in which event B is closed to preserve the vacuum and a few blows into A will dislodge the obstructing particles back into the stomach. The chief advantages of the glass bulb are that it prevents the soiling of the clothes or bedding, it lessens preliminary preparation, and renders assistance (Fig. 7) unnecessary in lavage or in the extraction of test-meals. The low suction method is to be employed in the extraction of test-meals while the high suction method is employed in lavage, particularly when performed at the bedside or the home of the patient. I have used this bulb in conjunction with the modified stomach-tube with the most gratifying results.

In conclusion, I desire to express my indebtedness to Dr. S. Wachsmann, Medical Director of the Montefiore Home, whose suggestions have aided me in the designing of the modified stomach-tube and the gastric glass bulb.

THE COMPLICATIONS OF PEPTIC ULCER.*

By J. N. HALL, MD.,

DENVER, COLO.

The complications of this affection have long attracted much attention. Their real significance is much better appreciated since the more general recognition of the definitely surgical character of chronic ulcer, and the consequent widespread study of the pathology of the affection as seen during life. Indeed, a fear of the development of some of the severe complications, using this term in its wider sense, leads the internist to advise operation much more freely than he otherwise would.

This study of the complications of ulcer is based upon an analysis of my private cases made by my associate, Dr. T. R. Love, and I shall first present this analysis briefly. Unfortunately, the records of my public hospital services have not been available for study because of their incompleteness.

*Read by invitation before the Buffalo, N. Y., Academy of Medicine, May 8, 1913.

During the past eleven years the diagnosis of gastric ulcer was made 188 times; that of duodenal ulcer, 78; a total of 266. The proportion of duodenal ulcers would be greater under present methods of classification, since all involving the pylorus were formerly classed as pyloric ulcers and included under the heading "gastric ulcer." Thus 61 of the first 93 operated cases were called pyloric, a majority being in fact probably duodenal.

Of the gastric ulcers 66 came to operation; of the duodenal ulcers 50. Acute perforation occurred 8 times (4 gastric and 4 duodenal). Chronic perforation had apparently occurred in several cases, but there was much difficulty in differentiation from severe adhesions of non-perforative origin. In 24 of the 66 gastric ulcers operated upon pyloric obstruction was due to scar or adhesions. The ulcer was active in the remainder, and in all but 6 compromised the patency of the pylorus, though not actually situated there in all. Hour-glass stomach was found in 5 cases at operation, and in one case not operated upon was exquisitely demonstrated by means of the bismuth plate. Multiple ulcers were found in 15 cases; in 8 of these there was a duodenal ulcer concomitant with one of the stomach; in the remaining 7 there were multiple gastric ulcers. The second ulcer may be a "contact ulcer," directly opposite the original one. In 3 cases not included here confidently diagnosed as pyloric ulcer, only a chronic appendicitis was found, and cure resulted from appendectomy. In several other cases the appendix was removed during an acute attack elsewhere and no examination of the stomach was made, so that the gastric diagnosis remains in doubt.

Cancer was proven 6 times with evidence of its origin from an ulcer. Very extensive tumor growth with adenitis was found in 4 other cases, but no gland was excised for histological examination. In view of the long history of ulcer the diagnosis of cancer was assumed. In one a gastroenterostomy was done because of the pyloric stenosis, and a fatal prognosis given. The woman remains well after four years, so that there was obviously an error in our conclusions. In a similar case in a male, recovery resulted. It is safe to withhold the diagnosis of malignancy in these cases unless proven histologically, for two surgeons of extensive experience, Drs. Craig and Freeman, agreed with me that the diagnosis of cancer was so evident from the gross appearances that it was best not to add to the patient's burden even by the excision of a gland. Suppuration of both parotids occurred in one case of gastric ulcer, and in one of duodenal ulcer, with recovery after operation in both. In another case death resulted from sepsis in connection with suppurative parotitis of one side. Gastric ulcer was found in two members of the same family three times. One pyloric ulcer was successfully operated upon during pregnancy.

We may consider first the troubles arising mechanically. The stomach becomes dilated either from pyloric spasm in case of active ulcer with hyperacidity, or, more commonly, from the presence of the swelling and consequent obstruction of an active ulcer, or, as seen at operation, yet more frequently from the scar of a healed ulcer. Such dilatation is probably the chief feature in leading to the resort to surgery. In my first 50 operated cases gastrectasis was present 30 times, and due to active ulcer, pyloric or duodenal, in 14 of these; to scar in 16. I believe that there is little justification for any prolonged medical treatment of pyloric ulcer with dilatation, since the healing of the lesion so commonly results in permanent pyloric obstruction, and as we shall see later, failure to heal so frequently leads to cancer. Stenosis of the cardiac orifice of the stomach rarely occurs, being very unusual as compared with pyloric stenosis, and unfortunately much less amenable to direct surgical relief. Marked prolapse of the stomach may be present, as the result of pyloric obstruction, due to the drag of the weight of the retained contents, the lessened strength of the supporting tissues and the pull of adhesions. In about 4 per cent. of the operated cases hour-glass stomach was found as the result of a chronic girdling ulcer. It may even be trilocular. The signs of hour-glass stomach are present and the interference with nutrition leads to surgical intervention. In one case Dr. Freeman successfully connected the upper compartment with the jejunum, this being the easiest operation on account of the serious adhesions, but in many cases the operative work may be confined to the stomach.

Marked duodenal stenosis is not uncommon. I have seen the duodenum contracted to such a degree and over such a length as to make it resemble the little finger in shape and size, with greatly indurated walls. Serious deformity of the stomach is very common, especially in saddle ulcer at the lesser curve, with great interference with its motility. Such deformity is caused in part by the adhesions so often found in the chronic indurative type of ulcer. The deformity may be the cause of the obstruction, without actual pyloric lesion. Many of the complications result from the extension of the ulceration, after a "protected" perforation, to adjacent parts. I have repeatedly seen portions of the liver or pancreas involved by such a process. In one case successfully operated five years ago, the larger portion of the pancreas projected into the stomach. The futility of medical treatment in such a condition must be apparent.

Perisplenitis may occur. The gall bladder is occasionally drawn into the mass of adhesions, and I have been puzzled to know, in such a case with puckered and shrunken gall bladder, whether the original process had been due to rupture of a cholecystitis into the stomach or of an ulcer into the gall bladder. Jaundice is a not very rare complication, in case adhesions compromise the common duct, and a chronic cholangitis may be established. While chronic pancreatitis is vastly less frequently found than in cases of gallstone disease, it is sufficiently frequent to deserve consideration. One very marked case occurred in my first 50 operated cases, and I have seen the complication occasionally since. The adhesions which are at times found uniting a healed ulcer to the anterior abdominal wall may be a source of great distress, apparently because of the constant pull exerted upon them, as the peristalsis and the variation in size of the stomach as it fills and empties vary the relations of the affected surfaces. Suppurative perigastritis will be mentioned later.

Perforation is a most prolific source of trouble. Occasionally one may detect the attempt at perforation through the occurrence of sharp pain, exquisite tenderness and rigidity, and frequently superficial hyperasthesia over the region affected. This may especially be the case when one has had the opportunity of watching the patient so that the general diagnosis and the new local abdominal signs are clear. Operation should be done at once to avoid the more serious troubles likely to follow. An advantage in early intervention is that gastroenterostomy or other curative operation may be done, as in certain of my cases, while after perforation it would be unsafe.

The acute peritonitis, commonly fatal within two or three days resulting from such perforation is well recognized. The greater peritoneal cavity is involved directly and suddenly, especially in perforation of ulcer of the anterior wall. Invasion of the lesser cavity is not infrequent, and is less readily recognized. I have mentioned elsewhere the occasional development of dry pleural friction just above the region of the spleen, due to diaphragmatic involvement, with extension through that organ and general pleural inflammation as a result. Empyema upon the left side is probably most frequently accounted for by such a process in case of peptic ulcer. Perforation into the bowel is not unusual, the gastrocolic fistula being most frequent. Perforation into the kidney has been recorded.

In general, the peritonitis excited by perforation of peptic ulcer is more severe, as the perforation occurs higher in the digestive tract, presumably because the duodenal contents are less infective than those of the stomach.

Subphrenic abscess of other type than the above is not very unusual. Osler estimates that 6 per cent. of the cases of this affection are due to perforation of duodenal ulcer, the abscess being commonly either in the right kidney pouch, or retroperitoneal. Probably twice as many are due to perforation of gastric ulcer. Although I have seen many cases of perforation of the diaphragm and lung by subphrenic abscess of appendiceal origin, I have seen but a single one due to gastric ulcer, and, indeed, that one was not absolutely proven, since an autopsy was denied. I have not seen perforation of the pericardium, although according to Pick this cavity is involved in about one-third of the instances of perforation of the diaphragm. Perforation into the mediastinal space with suppurative mediastinitis is a very grave and, fortunately, rare complication of ulcer. The following downward along the ascending colon of the abscess resulting from duodenal perforation should be noted since in many cases the appendix is charged with the symptoms. Only yesterday a case of mine was operated upon for duodenal ulcer with classical symptoms. The appendix had been removed several years before, presumably either because the symptoms of this same ulcer had been misinterpreted or else such a descending type of inflammation had led to an acute process which was wrongly thought to be of appendiceal origin. Many cases have been operated in the past without a sufficient exploration of the upper quadrant when the appendix was found to present locally a pathology inconsistent in its degree with the gravity of the general process. A peculiarity of the ulcerous type of subphrenic abscess is the frequency with which it is complicated with the presence of free gas. This should always suggest such an origin, although it is not infrequent in appendicitis and occasionally occurs in gastric cancer.

General septic invasion probably occurs more frequently as a result of localized burrowing of subphrenic abscess than in any other condition associated with ulcer. In one of my cases it resulted from a complicating parotitis. Perforation into the portal or other great vein is occasionally reported. Biliary colic due to obstruction of the common duct is not very infrequent, entirely apart from any disease of the gall bladder. It probably occurs as a result of (a) acute kinking or compression of the duct by the pull of adhesions, or (b) mechanical compression of the duct by the extensive induration of the duodenal ulcer. In several cases in which the attacks of colic were typical of biliary obstruction, we have found a very large and thickened ulcer involving the duct in its peripheral extension. This is not as commonly recognized a complication as most of those considered.

Hemorrhage may be so justly regarded as a symptom rather than a complication that we shall merely mention it. The severity of the hemorrhage from duodenal ulcer is such as to lead the careful physician to try to anticipate any serious results by the early recommendation of operation. I have seen several fatal cases in which earlier diagnosis and operation should presumably have been life saving.

The anemia following hemorrhage, especially frequently recurring chronic hemorrhage, is a feature of much importance. Although often of a mild secondary type it may so deplete the patient that death from apparently almost trivial intercurrent disease may occur. Such an anemia is a very frequent factor in the development of the neurasthenia, hysteria, and general enfeeblement so often found in advanced cases of chronic ulcer. The condition of lessened resistance in advanced cases of peptic ulcer leading to increased liability to tuberculosis, grippal pneumonia or other affections, deserves especial mention. I have seen many cases die from intercurrent diseases which should never have been permitted to reach such a state of lessened ability to withstand infection.

Vascular accidents are not very rare. Embolism and thrombosis are occasionally seen. In much depleted patients femoral thrombosis is to be feared, especially after the added shock of operation. I have not noted pulmonary embolism, but it may occur. Blindness, delirium and general convulsions may result from cerebral thrombosis. I have several times seen very ominous edema of the feet and legs without evidence of kidney involvement, and, therefore, presumably of hemic and circulatory origin, in patients who had delayed surgical interventon until much debilitated. In one woman who had lost a third of her weight such edema was the cause of much anxiety for a month after operation, although a full recovery finally occurred.

I have seen no mention in the literature of the frequency of arteriosclerosis as a complication of chronic ulcer. The long-continued indigestion with the throwing into the blood stream of the products of imperfect digestion and metabolism is a prolific source of arterial degeneration in

even comparatively young subjects. I have many times noted definitely palpable arteries in patients with ulcer before the middle of the fourth decade. The tendency to a widespread tissue degeneration in these cases has not received proper consideration. The not infrequent albuminuria and cylindruria are closely associated features and should be carefully weighed before submitting a patient with ulcer to further medical treatment.

The frequency of small central line abdominal hernia, especially between the navel and the ensiform cartilage in gastric ulcer is apparently too great to be accounted for as a coincidence. In general, the sac contains only a bit of the omentum, and I have seen an excellent surgeon insist until the neck of the sac was demonstrated, that such an omental hernia was but a small, fatty tumor. Pressure upon the hernia is commonly very distressing, and in two cases in which the hernia and ulcer were operated upon through the same incision, so that no doubt remained as to their character, pressure upon the hernia would result in such instant belching as to suggest the almost instantaneous action of an electric bell upon pressing the button. So far as I know, no explanation of the concurrence of the two conditions has been forthcoming. I am certain that the hernia should always be detected and operated upon in any case of ulcer demanding intervention if a cure is to be hoped for.

The occurrence of parotitis, not rarely suppurative, should be mentioned. It is of serious omen, but in two of this series recovery ensued after bilateral suppuration with operation. This complication is especially common after perforation of the ulcer. Rollestone states definitely his disbelief in the origin through infection by way of the salivary duct.

Although perhaps to be regarded wholly as a symptom, hiccough is so rarely mentioned that I wish to report its occurrence in one case over a period of eleven years, generally for a few weeks at a time, when the symptoms of gastric ulcer were undergoing an exacerbation, without a suspicion on the part of various physicians of its very direct dependence upon the ulcer. It was promptly cured by a gastroenterostomy done by Dr. I. B. Perkins. Puckering and adhesions about a saddle ulcer on the lesser curvature were present.

Jejunal ulcer developing as an after effect of a gastroenterostomy has been occasionally reported, but no such complication has to my knowledge been present in any of my operated cases, and improved technique seems to render it a less frequently reported complication.

The erosion of the incisor teeth by the acid eructations, notably in duodenal ulcer, as mentioned by Mayo, is a feature of interest.

The very frequent association of appendicitis with ulcer is worthy of consideration. In several cases there has been a clear history of an acute attack of appendicitis many years before, with chronic grumbling at intervals. Later the symptoms of ulcer appeared. To one who recognizes the very great frequency of acid indigestion as a result of chronic appendicitis, and of pyloric spasm, frequently associated with actual pyloric hypertrophy, the association of the two diseases would appear to be due to the development of the ulcer as a sequence of the chronic acid dyspepsia, resulting from the chronic appendicitis. The association of gallstone disease is probably rather the result of portal infection than an infection traveling to the gall bladder by way of the biliary passages, although the occasional blocking of the duct with its opportunity for infection in duodenal ulcer is worthy of very careful consideration.

Tetany has been more frequently reported abroad than in America. It occurs especially as a result of the gastrectasis, not primarily of the ulcer. I have not noted it in this connection. The occasional occurrence of pneumonia after operation for gastric ulcer has been mentioned by many writers. Acid intoxication is occasionally observed. A young and well-nourished nurse lost fifty pounds from an occluding pyloric ulcer. She was operated upon, but died toward the end of the first week after gastroenterostomy, as a result of this complication.

Most serious of all the complications of ulcer, and perhaps the most important in the consideration of the advisability of operation upon the pyloric variety, is cancer. I have seen the complication at operation many times, but the extensive statistics of the Mayos put all other reports in the background. "Sixty-eight per cent. of the pylori excised by the Mayos for cancer showed origin in an ulcer, while 71 per cent. of those excised under the belief that they were cases of ulcer showed cancerous changes beginning." (Wilson.) Under such a showing the physician assumes a weighty responsibility in withholding from the patient with chronic gastric ulcer the opportunity for surgical cure.

If operation were more frequently resorted to before more extensive pathological changes occurred, most of the complications we have studied would fail to develop. We need in the study of this disease, less an increase in our means of exact diagnosis than a fuller recognition that chronic peptic ulcer is a definite surgical affection, and curable by operation.

PREVENTABLE DEAFNESS.

By WILLIAM HIBBS TOMLINSON, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN DISEASES OF THE EAR, POLYCLINIC HOSPITAL; CHIEF CLINICAL ASSISTANT, EAR, NOSE AND THROAT DEPARTMENT, SAMARITAN HOSPITAL; CLINICAL ASSISTANT, EAR DEPARTMENT, PENNSYLVANIA HOSPITAL.

EVERYWHERE one goes one meets deaf people. What proportion of the population is afflicted with deafness to a degree incapacitating it from taking part in ordinary conversation no one knows. That the number of these unfortunates is great we must all admit. Comfort to the individual and usefulness to society is dependent in large measure upon communication with one's fellows by speech; thus the subject of deafness is worthy of study from the economic as well as from the humanitarian viewpoint. Many of these afflicted people take a steadily progressing hardness of hearing so philosophically as to consider their condition only a natural consequence of added years, even when a marked degree of deafness obtains by early middle life. Others dismiss the matter as due to heredity and submit most gracefully to what they consider their inevitable fate. Even the medical profession as a whole has been indifferent and needs awakening to its responsibility in this class of cases. The attitude of the profession and public is most important, for it

is only by a better knowledge of the subject that future generations can be benefited.

Deafness may be divided into two great classes: the one due to fault of the sound-perceiving apparatus and the other to fault of the sound-conducting apparatus. These are often spoken of, and quite properly, as nerve deafness and middle ear deafness. The sound-perceiving apparatus is made up of the internal ear or labyrinth with its complex system of special nerve endings, the auditory nerve proper, and the center for audition in the medulla oblongata. All these structures are deeply seated, well protected and not easily susceptible to outside influences. The sound-conducting apparatus is made up of the external ear and the middle ear, which latter includes the tympanic cavity with its chain of ossicles, the drum membrane, mastoid cells and eustachian tube. The structures composing the conducting apparatus are more superficially situated and are directly exposed to infection from without the body by way of the unbroken mucous membrane which lines the nasopharynx, eustachian tube, middle ear, and mastoid cells.

Middle ear deafness comprises some 80 to 90 per cent. of the total number of those who come to the physician for help because of failing power of the auditory sense. In all but a very small percentage of cases of middle ear deafness the condition is a secondary one, the primary disease being some degree of inflammation affecting the nose, pharynx, epipharynx, and by continuity involving the eustachian tube and middle ear. There is only a small percentage of cases in which the nasopharynx plays no part. These cases may be due to trauma, to infection directly from the external ear through the drum membrane, or to infection directly from the blood stream. In a few instances there is no inflammatory basis, vasomotor changes dependent upon constitutional disturbances being the causative factor.

There is, then, a great class of ear cases, of which the total number is an overwhelming majority of all ear cases of every kind, in which deafness in some degree is due to varying grades of inflammation, either past or present, involving either the middle ear, eustachian tube and mastoid cells, or the eustachian tube and middle ear without mastoid involvement. This group includes both the acute and chronic forms of suppurative and non-suppurative otitis media, and broadly speaking all are due to inflammations in the region of the pharyngeal end of the eustachian tube, by extension resulting in eustachian salpingitis and finally in middle ear disease. As concerns the causative factors the suppurative ear diseases differ from the catarrhal only in the kind or virulence of the infecting organism invading the nasopharynx, or, again, the difference may be in the resisting power of the individual affected, similar organisms producing in one suppurative, in the other catarrhal, disease only. Of all the conditions responsible for this train of inflammations, adenoid tissue in the epipharynx is the most common predisposing cause. Murray, in a most comprehensive article read before the Section on Otology, Laryngology and Rhinology at last year's meeting of the American Medical Association, dealing with the responsibility of conditions in the nose and throat as concerns middle ear diseases, placed the proportion of adenoid cases in children complicated by ear involvement at 30 per cent. He adds, however, that the percentage will be much higher if careful objective aural examinations are made and changes in the appearance of the drum membrane noted. The writer is convinced of the truth of this assertion and from routine examination in adenoid cases he believes that 75 per cent. have ear involvement. Changes in the contour of the membrane or in its translucency are the departures from the normal most often noted and these are evidences of deficient aeration of the middle ear even though subjective symptoms are not present. Again, quoting Murray, the writer agrees with him that many cases of chronic catarrhal otitis media that apparently have had their inception in adult life are in reality the result of a diseased condition of the nasopharynx existing during childhood.

It is not hard to understand why adenoid tissue is responsible for so many of these cases. The adenoid mass consists of irregular lobes and lobules of lymphoid tissue situated in the epipharynx directly between and adjoining the eustachian orifices and in direct line with the air current with its content of various irritants and microorganisms. A vascular tissue, capable of rapid and considerable swelling and divided by irregular sulci that offer ideal sites for the lodgement of débris and infective organisms, it is no wonder that it is subject to recurring inflammations. In children the position of the eustachian tube, too, favors infection, it being more horizontally placed and more nearly straight than in the adult and with a relatively wider mouth. This anatomical difference accounts somewhat for the frequency of ear complications in early childhood when so slight a disturbance as that accompanying dentition seems the only cause of a suppurative otitis.

Among other conditions predisposing to eustachian involvement are diseased faucial tonsils, chronic follicular pharyngitis, adhesions in the fossæ of Rosenmüller, accessory sinus disease, and intranasal obstructions. The faucial tonsils may be responsible both by reason of repeated inflammations with extension and by pressure interfering with the action of the palatal muscles and the mobility of the eustachian tube. In accessory sinus disease, and particularly in postethmoidal and sphenoidal empyema, the course of the flow of pus makes the reason for eustachian involvement obvious. Intranasal obstruction predisposes principally, according to Ballenger, by causing just behind the obstructions areas subjected to lessened air pressure; there is therefore more or less stagnation of blood with consequent lessened vitality of tissue, predisposing to infection. Murray, in speaking of this subject, brings forward statistics showing that in middle ear disease with nasal obstruction the ear showing the more marked deafness is always on the side of the nasal obstruction. The acute infectious diseases also predispose to ear involvements, influenza and the exanthemata of childhood being especially prone to this complication.

The diagnosis of the acute middle ear diseases causing deafness is of course made upon the history of the cases, by the constitutional symptoms and by finding the signs of inflammation upon inspection of the tympanic membrane. In the milder grades which stop short of middle ear involvement there are no tympanic signs and diagnosis rests upon the deafness, tinnitus, and partial or complete occlusion of the eustachian tube. In the chronic forms middle ear deafness is differentiated from nerve deafness by the changes in the middle ear and tympanic membrane, by eustachian involvement, and by functional

tests with watch and tuning forks, these showing relatively increased sound perception by bone conduction with decrease by air conduction, thus proving the integrity of the sound-perceiving apparatus.

Non-suppurative otitis media is amenable to treatment inversely to the degree of deafness and the length of time it has been present. In the acute forms, either with or without secretion in the middle ear, the prognosis is good for recovery of normal hearing under proper constitutional and local treatment. Without treatment recovery may take place, or a mild degree of inflammation may persist and the condition assume the chronic form. The prognosis in the long existent non-suppurative conditions depends greatly upon the extent of the pathological changes in the middle ear and particularly upon the degree of fixation of the chain of ossicles and tympanic membrane. If this is marked the degree of improvement will be slight, but if a considerable degree of motility is present, or can be secured, the prognosis is good for relief from the tinnitus and for a considerable improvement in hearing.

From a not inconsiderable experience the writer is convinced that the routine treatment of these chronic cases as conducted in many hospitals is entirely inadequate and incapable of doing the good that should be accomplished. With the large number of patients clamoring for treatment in our dispensaries and the limited time at our disposal for their relief it is perhaps surprising that so much good is, in most cases, accomplished. It is an unfortunate fact that we are obliged to treat these patients not as individual cases, but routinely with Politzer bag and massage instrument. In probably one-half to three-quarters of these cases the use of the Politzer bag does not mean that the middle ear is inflated. The patient's statements that he feels it in both ears are unreliable, as can easily be verified by any one so inclined. The use of the auscultation tube gives the operator positive evidence as to whether inflation takes place or not and gives, also, by the character of the sound heard, knowledge concerning the condition of the eustachian tube, the operator distinguishing between the soft blowing sound of the freely patulous tube, the râles heard when secretions are present and the various higher pitched notes of obstruction by adhesions and strictures. In all such cases the eustachian catheter should be used, for by this means air may be made to enter the middle ear and good be accomplished. With recent improvements in the technique of eustachian maneuvers, notably by Yankauer of New York and Holmes of Boston, the field of eustachian treatment and surgery looms up as an important one for future work. The next half dozen years will undoubtedly see a marked degree of improvement in our treatment of both these great chronic classes, non-suppurative and suppurative otitis media.

In conclusion the writer desires to state, what is already evident, that he has not endeavored, nor has he desired, to present an exhaustive or strictly scientific paper on the subject of deafness. The question is a complex one and its many phases should each receive our most thorough study. He has rather felt that the subject needs reiteration, that we need occasionally to have it brought forward in a general way, so we may look toward improvement in our work and a consequent greater usefulness to our patients and the public. The few points he would particularly emphasize are these: (1) Middle ear deafness comprises about 80 to 90 per cent. of all forms of deafness. (2) Ninety per cent. of the cases of middle ear deafness have their origin in inflammatory conditions of the nasopharynx with extension to the ear by way of the eustachian tube. (3) Adenoid tissue in the epipharynx is the most frequent predisposing cause of middle ear disease. (4) Systematic aural examination in adenoid cases discloses the fact that a high percentage, probably 75 per cent., have some grade of ear involvement. (5) The findings of routine ear examination in children with adenoids confirms us in the belief that many cases of middle ear deafness first noticed in adult life have their origin in inflammatory conditions of the nasopharynx, dating from childhood. (6) The milder acute forms of catarrhal otitis should receive appropriate treatment, for if untreated they are liable to assume the chronic form. (7) Routine treatment of chronic catarrhal deafness leaves much to be desired. More careful work is necessary if the best results possible are to be secured. (8) This is an age of preventive medicine. Possibly in no other field is there better opportunity than in the prevention of chronic middle ear disease and its deafness.

1212 Spruce Street.

ALASKA AND ITS HEALTH.

By ALFRED C. REED, M.D.,

POMONA, CALIF.

Alaska, the Norway of the new world, is a region unknown and strange to most men. Its vastness is unappreciated. Its wonderful resources are not considered. Its strange peoples and their stranger customs are seldom described. More remarkable still, its matchless scenery and unsurpassed beauty of mountain and fiord are only now beginning to claim the tourist and vacation-seeker. The name itself is a corruption of the native word, "Al-ay-eksa," meaning a great country. And without doubt it *is* a great country—one-fifth as large as the continental United States, 600,000 square miles in area, stretching from Point Barrow at the 72d parallel, to Prince of Wales Island at the 55th.

Geographically it is separated into two portions by Mount St. Elias, a noble crest towering 18,000 feet above the sea. The southeastern portion is the coast strip which reaches well down toward Seattle. Fiords of the greatest beauty run deeply into the precipitous coast ranges here, and toward the Pacific are protected by numerous densely wooded islands, so that from Seattle to Dyea there are but few miles of open sea. Western Alaska embraces the great bulk of the district. Towering mountain chains, large lakes often set in wide-spreading swamps, and beyond these a bleak Arctic Sahara—such is the country here.

Switzerland is outdone by the glaciers of Alaska. Remarkable indeed is the majestic Malaspina, a vast elevated plateau of wasting ice, 1,500 square miles in extent, one-tenth the size of Switzerland itself. The Malaspina is fed by many lesser glaciers, among them the Seward, coming 50 miles in its course from Mount Logan, and spreading three miles in width at its narrowest point. The Seward has several ice cascades dropping hundreds of feet in its course.

Great extremes of temperature prevail, 80° below zero has been recorded, while the brief summer may see the mercury well over 90°. Along the coast frequent rain and fog are responsible for heavy vegetation, and the ports of Juneau

Sitka, and Dyea are open to navigation the year round.

A Russian expedition headed by Chirikov and Captain Vitus Behring discovered Alaska in 1741, and at once fishing and fur-trading posts were established along the coast. A charter was granted by the Emperor Paul in 1799 to a Russian-American fur company, and was renewed in 1839 when Sitka became the principal settlement. No one dreamed in those days of gold. Fur and fisheries were all-important.

In 1867 the whole of Russian America was bought by the United States for $7,200,000. Secretary Seward, who was responsible for the purchase, was bitterly blamed at the time for his folly, and "Seward's ice-box" was a by-word. But fortunately Seward's prophetic wisdom prevailed. Asked by a friend, not long before his death, what he considered his most important political act, the reply was, "The purchase of Alaska, but it will take the people a generation to find it out." The people are finding out now what Seward foresaw in 1867, but in the meantime scant attention and little aid have been extended to Alaska, and in no particular has this neglect had less excuse than in regard to health conditions among Alaskan natives. These natives number about 25,000, scattered over a vast territory in villages of from 25 to 300 persons each. Four ethnologic types are represented: (1) The Eskimo or Innuit, of which the Aleut is an offshoot; (2) the Haidas or Kaigan who live chiefly on Prince of Wales Island and its vicinity; (3) the Thlinkets, and (4) the Tinnehs or Athapascans, the stock race of the great interior country. The native villages are, as a whole, very inaccessible. The ordinary means of travel is by boat, and during the long winters dog teams afford almost the only means of communication.

Our treatment of Alaska stands in singular contrast to the policies which have transformed the Canal Zone, Cuba, and the Philippines from tropical pest-holes into sanitary, safe, and productive territories. With every advantage of undeveloped wealth, freedom from endemic disease, and healthy climate, Alaska has been allowed to drift into a sanitary condition which disgraces our proved prowess in this realm elsewhere. It ought now to have a place with our other dependencies, as a model of sanitation, and a monumental triumph of scientific preventive medicine. But Alaska is far from such a state.

At the request of the Secretary of the Interior, a medical officer was detailed from the federal Public Health Service in April, 1911, to make a study of disease in Alaska, and of the conditions favoring its spread, with a view toward inaugurating adequate measures of prevention. This timely and difficult task was assigned to Dr. M. H. Foster, and his thorough and scientific investigation has been made the basis for active measures for the medical relief of the Alaskan natives.

From the standpoint of the sanitarian, one of the most serious conditions lay in the housing facilities. While the dwellings were well built and substantial, they had practically no provision for ventilation, and were, as a rule, entirely too small for the number of occupants. Overheating, overcrowding, and lack of ventilation were very conductive to the spread of diseases, especially such as tuberculosis. No attempt is made by the natives to dispose of garbage and household refuse. It lies where it falls, but after all this is an esthetic rather than a sanitary offense in such a climate.

The staple article of diet is fish, and no sea product is more dearly loved or more widely used than fish oil. This fish oil is made by filling pits with masses of fish, which are left until putrefaction begins. Then the ill-smelling mass is dug up and placed in canoes together with water and hot stones. As the oil comes to the surface it is skimmed off and stored for future use. Not only is this fish oil an important article of diet, but it is also used liberally for external application. The consequence is that the natives smell horribly and cannot even be admitted to white wards in the hospitals because of the overpowering stench. Digestive troubles are of frequent occurrence because their food is commonly bolted, and over-eating in times of plenty alternates with starvation in times of want.

The outdoor occupations of fishing and salmon canning are healthful. In most of Alaska the ablebodied can make a living if they are industrious. Poor management and laziness, however, stand in their way, and the Indian is by nature improvident. The effects of alcohol are as destructive as among other primitive peoples. The most serious condition is the lack of a suitable water supply in most of the villages. In only a few is water of good quality piped to the village in abundant quantity. Good water is almost always available and in sufficient amount, but the fact that it must be carried from well or spring by hand and often up-hill is an insurmountable obstacle to the Alaskan, whose nature abhors physical exertion. In the extreme north melted snow is the chief source of water. The result of these conditions is that, especially above the Arctic Circle, urine is commonly used for personal ablutions, and decomposed urine for washing clothes, both on account of the lack of a good water supply and because of the ammonia contained. This is paralleled by the practice of the natives of Anadir across Behring Strait in Siberia, where urine is employed in a sort of Turkish bath.

Some villages depend for their water supply on seepage water from the surface, a dangerous and precarious source. In spite of this, water-borne diseases are extremely rare. It is worse than useless to expend money and effort in teaching cleanliness and personal hygiene when there is no water with which to be clean. Foster considers that government funds could be spent in no other way so advantageously as in providing a suitable water supply for native villages. He cites the great improvement which followed the efforts of the resident missionary at Klukwan, who through the generous aid of an Eastern philanthropist, piped water through the settlement. Excellent springs and streams are numerous, and a small fund would do great good.

The diseases most prevalent among Alaskan natives are tuberculosis, syphilis, and trachoma. These are causing great ravages. The native Alaskans have no heredity of immunization, such as falls to civilized races today, and disease takes a virulent course. Foster examined 1,364 natives himself, and checked his results by the observations of local missionaries, teachers, physicians, and government officials. He found 0.5 per cent. to have active syphilis, and 5.3 per cent. showed symptoms indicating the disease in a latent or hereditary form. The disease yields readily to treatment, but continued

treatment is almost impossible outside of an institution because the Indians will not carry out directions or submit to control otherwise.

Pulmonary tuberculosis is not so common as might be expected from the personal habits, housing, and lack of hereditary immunity. Foster rightly believes that the high fat content of the diet, consisting so largely of fish oil, has a definite rôle in increasing the resistance to tuberculosis. At the present rate, sixty or seventy years will see the last of these natives. The death rate now is about 85 per thousand, as compared with an average of about 22 per thousand for the United States. The birth rate in Alaska is high, but not nearly in proportion to the death rate. This enormous death rate is in no small degree due to tuberculosis. Foster considers it hopeless to attempt to care for the tuberculous except in proper sanitaria, and his suggestion in this regard merits serious consideration.

Eye diseases of all kinds are very common, over 16 per cent. having some such disorder. Half of these were trachomatous. In some sections more than half of the population suffered from trachoma. The blind are seen everywhere, and a government home is badly needed for these as well as for destitute and helpless cripples, all of whom receive scant sympathy from their fellows and have no employment.

Foster concludes that apparently little lasting effect can be expected from a campaign of education and moral suasion. More vigorous measures are demanded. Alaska should have a commissioner of public health to enforce a thorough sanitary code. Authority has been asked for the surgeon-general of the Public Health Service to appoint one of the officers of that corps to serve in such a capacity. In accord with this suggestion, Dr. Emil Krulish has been detailed for this duty and has assumed charge of measures for the medical relief of the natives.

It has been a slow awakening to Alaska's need and to our obligation as a nation. Great things must be done. They can be done as they have been done elsewhere. Every American should have an intelligent pride in the wonders and resources of Alaska, as well as a conscious obligation to further by every possible means the measures now being inaugurated in behalf of the Alaskan natives.

720 East Holt Avenue.

UNILATERAL AMBLYOPIC AND DIPLOPIA FOLLOWING SUPPRESSIO MENSIUM.

By S. LATIMER PHILLIPS, M.D.,

SAVANNAH, GA.

Many authors have noted a connection between impaired functions of the female sexual organs and the organs of vision, symptoms having varied from a slight irritation of the eye to complete loss of vision. That sudden suppression of the menses should have its effect upon the eye is not surprising when we consider the shock to the whole system. The case reported below is especially interesting in that only one eye was affected. Most of the cases I could find reported had both eyes involved.

Miss ———, 41 years of age, apparently in the best of health, consulted me May 24, 1912, with the history of almost entirely having lost sight of left eye during the preceding three weeks. $V = R \frac{15}{x}, L \frac{15}{cc}$. Eye had sensation of "over fullness." There was some pain in moving the eye about, and when the ball was pressed firmly back into the socket. Neuralgia in left side of face and head, so severe in lower jaw I had her consult a dentist, who found an exposed nerve, afterwards filling the tooth. Some protrusion of eyeball, normal. Mobility of eyeball outward impaired. She had been doing quite a lot of fine needlework which she thought might have had some influence on her eye. Being energetic she was in the habit of stirring around considerably, getting overheated, then sitting down with her sewing before a large open window opposite an open door, with a strong breeze blowing through. A little over three weeks before coming to me, when her courses were on, she did this; after one day, menstruation ceased, and the eye began to get painful and lose sight. Thinking the eye would improve every day she put off seeking help as long as possible. Ophthalmoscopic examination: R normal, L large peripheral spot of choroidal atrophy of 15 years' standing. I head treated her at that time with good result. $V = L \frac{15}{xv}$. Besides the above condition there was only light infiltration of optic nerve and retina, with veins fuller than normal. At once three leeches were applied to left temple. Hot foot bath at night with 2½ gr. each of calomel and soda. Condition seemed no better on the 25th. I then ordered potassium iodide gr. X, t.i.d., with very hot sitz bath every night. On the 28th menstrual flow returned, and has been regular ever since. Vision began slowly to return. On June 8 $V = L \frac{15}{lxx}$. As vision began to improve she observed diplopia, but this, too, got better and she noticed it only when looking to left. On July 8 vision in left eye was $\frac{15}{xv}$. She continued to take potassium iodide until July 25 when it was discontinued. $V = R \frac{15}{x} L \frac{15}{xv}$. Reads and sews in moderation and has had no further eye trouble save a slight attack of catarrhal conjunctivitis in right eye this last Spring.

Samelsohn explained these cases by the sudden closure of the uterine vessels, overfilling the blood stream, which lead to extravasation and transudation, and consequent compression of the optic nerve. Similar cases we meet with in circumscribed hemorrhage in the substance or sheath of the optic nerve whereby the conducting power of the nerve is completely cut off. On the other hand Mooren believes in a central cause—basing his supposition upon the orbital pain—which might be explained in a natural manner by a simultaneous compression of the root of the trigeminus.

232 Bull Street.

Myeloid Leucemia and Tuberculosis.—Otto Roth cites a number of cases including his own that seem to show a close association between tuberculosis and myeloid leucemia. According to Nana tuberculosis may under certain circumstances be the main causal factor in the production of chronic myeloid leucemia. This etiological sequence is regarded by the author as all the more probable in the case of acute myeloid leucemia.—*Zeitschrift für klinische Medizin.*

The Water Requirement of the Infant.—L. F. Meyer points out that the living tissues consist of more than one-half of water. In the growing organism water plays a more important rôle than in the full-grown animal. It was shown by O. and W. Heubner that an inadequate gain in weight in nursing infants is often to be attributed to an insufficient supply of water to the infant. In an experimental investigation conducted with the view of testing this observation the author succeeded in differentiating three groups of children: (1) Those fed on a concentrated and sweetened preparation of casein- milk, who lost in weight and gained only when water was added to the diet. (2) Children that on a similar diet maintained a stationary weight and gained only on the addition of water. (3) Children that on a concentrated diet thrived and gained in weight, but that at the end of a number of weeks attained a stationary weight; at this stage the addition of water to the diet was followed by an increase in weight. The following practical rule is laid down: An infant needs on an average daily 150 grams of water for each kilogram of body weight.—*Zeitschrift für Kinderheilkunde.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, September 27, 1913.

EPIDEMICITY OF LARYNGEAL DIPHTHERIA.

ONE of the most interesting and baffling facts in connection with the prevalence of infectious diseases is the varying virulence and epidemicity of these diseases from year to year. This was observed most strikingly in Germany about two years ago when diphtheria attained an unusual degree of virulence and diffusion, in spite of prompt and thorough antitoxic treatment. Still more remarkable is the fact that diphtheria of the larynx considered apart from diphtheria of the pharynx is subject to certain unusual degrees of prevalence and severity. The occurrence of a large number of cases of diphtheritic croup in the city of Naples during the past eleven years enabled Alfonso Montefusco to record a number of interesting data pertaining to this subject (*Giornale Internazionale delle Scienze Mediche,* August 31, 1913).

A most unusual phenomenon observed in Naples was the relatively large proportion of cases of diphtheritic croup as compared with the cases of diphtheria in general. In the Cotugno Hospital from 1902 until 1912 there were treated 2,464 cases of diphtheritic croup, and 539 cases of diphtheria in which the larynx was not affected. The mortality in the former group was 25.3 per cent. In the latter group the mortality was 8.8 per cent. The greater frequency of diphtheritic croup as compared with pharyngeal diphtheria might be explained on the supposition that many of the milder pharyngeal cases are not reported to the sanitary authorities and hence do not appear in the statistics. Moreover, a greater proportion of the croup cases are undoubtedly sent to the hospital, so that figures based upon hospital admissions would be apt to show an unduly large percentage of croup cases. Nevertheless, even if one admits these facts, there can be no doubt that in the city of Naples during the past decade laryngeal diphtheria was the predominating type of this disease.

How can this extraordinary fact be explained? It might be advanced that in Naples the Klebs-Loeffler bacillus has acquired a peculiar virulence. This supposition can be dismissed with the statement that although croup cases are much more fatal than ordinary cases of diphtheria, this greater severity is not due to any greater virulence of the infective organism but is the result of the anatomical conditions which render so ominous even a mild membranous invasion of the larynx. Moreover the mortality of 25 per cent. which characterized the cases of croup in Naples compares most favorably with the mortality figures with reference to this disease in other parts of the world. One can therefore leave out of consideration any question as to the relative virulence of the germ. There is some unknown factor which seems to preside over the anatomical distribution of the diphtheritic process. A close analogy is afforded by the study of plague. In most of the epidemics of this disease the bubonic type is the predominating if not the sole type. On the other hand there are epidemics in which the pulmonic type is the prevailing one. No explanation has yet been forthcoming as to why the *Bacillus pestis* at certain times and in certain localities invades the lungs rather than the lymphatic system. The same selective anomaly applies to the diphtheria bacillus. There is one difficulty that may be explained in the case of the anatomical distribution of diphtheria. One should distinguish between cases of membranous laryngitis which are the result of an extension by continuity of the diphtheritic process from the pharynx, and cases of membranous laryngitis which are primary, or, in other words, which start in the larynx. It is to the latter group of cases to which should be confined the study of the factors which underlie the anatomical distribution of the diphtheritic membrane. Conkey has pointed out that in cultures of diphtheria bacilli there is a greater production of toxins during the period from the end of September to the end of March. There is thus a parallelism between the incidence and mortality of diphtheria on the one hand, and the production of toxins in cultures of the diphtheria bacillus on the other hand.

The large number of cases of laryngeal diphtheria that were studied by Montefusco enabled him to glean other important data relating to the epidemiology of this disease. It is least frequent and has the least mortality from the first to the seventh month of life. After this period the frequency increases up to the first year, when it attains its maximum frequency. This continues until the second year of life, after which time the frequency gradually diminishes up to the fifth year. Beyond the fifth year the incidence of croup rapidly diminishes. The curve of mortality is parallel to the curve of incidence. Croup is more frequent and more fatal among males than among females. It is relatively more common in rural than in urban communities but there is no marked difference in the mortality in comparing city and country. The incidence and mortality of croup are in general greatest during the period from December to March, and least during the summer months.

SECRETIN.

WHEN it is considered that not more than thirty years have elapsed since Brown-Séquard first advanced the view that the internal secretions might play an important part in the working economy of the human system, the progress made in the eluci-

dation of the obscure points with regard to this theory has been on the whole satisfactory. Brown-Séquard, although he had probably grasped the right idea, to a large extent was groping in the dark and the extraordinary development in this branch of physiology owes much to the investigations carried out by Pavlov in the Institute of Experimental Medicine at St. Petersburg. Pavlov cleared up many of the biological facts, and other investigators, notably Starling of London, have set themselves to the study of the chemical and physical conditions which determine the digestive changes in the foodstuffs and to the means whereby the pancreas is excited to secrete. Starling, in his recently published "Physiology," explains lucidly and succinctly both these matters and further unfolds several more leaves of this hitherto closed book. Much has been learned of late years regarding the relation of the internal secretions to most parts of the body and especially of their relation to the intestinal tract, to which branch of the subject Pavlov, Edkins, Baylis, Starling, Dopielski, Wertheimer, and others have particularly devoted themselves, nor must the labors of Sajous in this field be overlooked.

When Pavlov made the discovery that the pancreas is normally excited to secrete in response to stimuli originating in the gut, he thought that the stimuli were afforded by means of the nervous system. But Starling with the assistance of Baylis found out that the nervous system did not provide these stimuli, but that they were supplied by the dispatch of a chemical messenger or hormone from the seat of stimulation to the reacting gland through the blood stream. Moreover, subsequent investigations have demonstrated the existence of other chemical correlations of the same nature, and, as Starling says, suggest that by the detection and isolation of such hormones we may later be in a position to influence and control a number of the chief functions of the body. Starling has named the hormone, or exciting agent which arouses the intestinal ferments to perform the proper functions, secretin. This substance may be formed from mucous membrane by the action of any acids or even by simply boiling the tissue with water. On the other hand, mere extraction with cold water or alcohol, in which secretin is freely soluble, does not result in the production of an active solution. As an outcome of these investigations Starling concludes that the epithelial cells lining the gut contain a body, prosecretin, which is insoluble in water or salt solution, but which, under the influence of agents such as acids, undergoes hydrolysis with the formation of a new body, secretin. Consequently when hydrochloric acid is introduced into the small intestine it acts on the prosecretin and produces secretin, which in turn causes a flow of the pancreatic secretion necessary to proper digestion. The physiological reason for the flow of pancreatic secretion is that by the agency of the HCl in the chyme secretin is produced and this is absorbed into the circulation and borne in the blood stream to the pancreas where, as said before, it acts as a specific stimulus to the secretory cells. It is also confidently assumed, if not absolutely proven, that secretin excites the secretion of bile by the liver-cells and the secretion of intestinal juice by the glands of the intestine.

UNMARRIED MOTHERS.

Edith Livingston Smith contributes a very remarkable article to *Harper's Weekly* of September 6, 1913, on various social aspects of "unmarried mothers." The author does not use any circumlocution in handling a subject in which the new feminist movement is so deeply interested. So-called maternity homes are condemned for three reasons: Their atmosphere is abnormal. The prospective mother needs expert obstetrical care at the time of her confinement, and it is difficult to combine medical efficiency with professional charity. These "homes" are economically inefficient in not yielding the best results for the money expended. As a substitute for the maternity home the author would keep the pregnant girl in her own home until she can go to a lying-in hospital for her confinement. If such a girl cannot stay in her own home she should be placed in some family under the care of a good and sympathetic woman. The author holds that just as the institutional care of orphans has failed, so has the institutional care of unmarried mothers.

After reading this rather sensible presentation of a subject which seems to be nowadays regarded as a fit topic for discussion in the family circle, one is somewhat startled by the sudden interjection of a modern fairy story in the guise of a report of what the author would have us believe is a "typical" case of the unmarried mother. "Pretty as a picture, impulsive, and outspoken," Louise has syphilis and gonorrhea (ulcus molle was apparently overlooked) and is pregnant besides. The father of her child and the one she loves is a college graduate. (All bad men nowadays are "college graduates"—usually, we believe, from Harvard.) Another man, James G., wants to marry her "to save her from her fate, and to protect her and her unborn child." He will not live with her until she is cured (wherein he shows a modicum of common sense); he will even wait for her as her husband three years. So Louise marries honest James, but she still loves the "college graduate." The author asks: "What is morality? Living with a man one does not love because of a wedding ring upon the finger? Bearing the child of a man she does love who will not shield her from their mutual folly? Poor Louise!"—Poor James G.! The pathetic tale furnishes abundant material for a modern sex drama, absolutely guaranteed to draw crowded houses from the ranks of men and women who are far beyond the need of instruction in the problems of sex and the danger of lax morals.

An Official Warning Against Dangerous Diet Cranks.

Of all the numerous diet systems, the advocates of which plague the average citizen with their vociferous claims and persistent advertising, one of the most illogical, inconsistent, and dangerous to health is the raw food faddism. The high priests of that cult and of others nearly as

back, whether fakers or just cranks, have been making of themselves such nuisances that people all over the country have written to the Agricultural Department calling its attention to the misstatements in the advertising literature and seeking protection from the annoyance. In response to their requests the specialists in the Department have issued a statement warning people against adopting the dietary recommendations of persons having no scientific standing. In most of the arguments of these self-styled "experts," the statement says, there is hardly a shadow of reason, though they may seem plausible. An example is cited of a raw-fooder who fed rabbits on cooked food exclusively and found they did not thrive, and therefore, with admirable logic, offered the conclusion that human beings should confine themselves to raw food. Not only is the fact ignored that civilized man for ages has cooked the greater part of his food and that his palate and his digestion will accept only a few raw things, but the danger in raw foods of infection with pathogenic microorganisms and infestation with intestinal parasites is never mentioned, probably because unknown to these faddists. Another assertion made by them —for of course, like most diet cranks, they abhor meat-eating, corpse-eating as they call it—is that meat is filled with bacteria. But it is tiresome to catalogue the absurdities of these diet cranks who pick up a few isolated facts or bizarre notions and attempt to base on them a system of living adapted to all sorts and conditions of men. The Agricultural Department does well to warn the people against all these fantastic diet systems.

News of the Week.

Local Epidemic of Typhoid Fever in New York.—From September 3 to September 20 178 cases of typhoid fever have been reported from the district east of Third Avenue between Sixth and Thirty-third streets. There were on September 21, 210 cases of the disease in the city. There are 72 cases in Bellevue Hospital,more than have been in that institution at one time in half a century. The Health Department has succeeded in tracing the source of some of the cases to a certain milk supply and will continue the investigation until the dairy from which the infected milk comes has been discovered. Immunizing treatment is offered by the Health Department to families one of whose members has the disease, but the east-siders are not very desirous of availing themselves of this offer.

Cholera in Roumania.—It is reported that there have been 1,200 cases of cholera, with 45 deaths, in Bucharest during the past fortnight.

Fewer Medical College Graduates This Year.—The number of graduates from the medical colleges of this country for the year ending July 30, 1913, was 3,981, a decrease of 502 as compared with the previous year, a decrease of 202 below 1911, and a decrease of 459 below 1910. The total number of graduates this year was 1,166 less than in 1904. There were 209 graduates from the homeopathic colleges, or 57 more than in 1911. The eclectic colleges graduated 93, one more than in the previous year, but 17 less than in 1911. About 20 per cent. of the graduates of the regular medical schools had baccalaureate degrees, while in 1911 but 15.3 per cent. were reported as holding such degrees. Of the 753 graduates holding baccalaureate degrees, the largest number, 139, came from Illinois colleges, while 99 came from New York, 80 from Maryland, 73 from Pennsylvania, and 60 from Massachusetts.

Changes at the Army Medical School.—Orders issued at the War Department on September 9 relieve Col. Walter D. McCaw and Major Charles R. Reynolds from further duty at the school. Col. Champe D. McCulloch, Jr., is assigned to duty as professor of military and tropical medicine; Lieut.-Col. James D. Glennan, as professor of the medical department administration; Major Eugene R. Whitmore, as professor of bacteriology, pathology, and clinical diagnosis, and Captain Edward M. Tabott, as assistant professor of ophthalmology.

Registration of all Births Urged by Government.—A bulletin issued by the Government Children's Bureau at Washington, D. C., has been sent to all the States asking that laws for the adequate registration of all births be passed by the States. The bulletin points out that in Arkansas, Georgia, North Carolina, and South Carolina there are absolutely no laws for the registration of births. In sixteen States, including New York, New Jersey, and Wisconsin, there are adequate laws that are not enforced, while in twenty States, including Illinois, Indiana, and Iowa new laws and amendments are necessary.

The Harvey Society Lectures.—The first lecture of the Harvey Society will be given on Saturday, October 4, at the Academy of Medicine at 8.30 P.M., by Dr. Augustus D. Waller, of the University of London. His subject will be "A Short Account of the Origin and Scope of Electrocardiography." Dr. Waller brings with him from London his own apparatus with which he will give demonstrations during the lecture.

A Pettenkofer Memorial.—In the *Muenchener medizinische Wochenschrift* for August 26 there is a brief account of a medical building, the Pettenkofer House, which is intended to serve both as a monument to the great sanitarian and as a home for the medical profession. At present the plans are being drawn, all the local medical societies having united to carry out the project. It is hoped that the next session of the International Medical Congress, which meets at Münich in 1917, will be able to hold its general sessions in the great auditorium of the Pettenkofer House. The latter will also be open to visiting medical men. The large library and reading room of the Aertzlicher Verein will be moved into the new building. Much of the required funds will be raised by Government lottery.

Cancer Statistics in Norway and Elsewhere.—Careful study of the remarkably accurate data gathered by the Norwegian cancer committee show for that country two remarkable variations from the figures for the rest of the world. More men than women died of cancer in Norway, and cancer of the stomach is the most prevalent form, death from this form of cancer ranging from 63 to 74 per cent. in different provinces. Again the incidence of cancer in women is markedly different from that in other countries. These findings suggest that cancer is more influenced by habits of life, food, and external surroundings than has been supposed possible. The cancer statistics from the registration area of the United States show that there were 44,024 deaths from cancer in 1911 or a death rate of 74.3 per 100,000 population. The rate for 1910 was 76.2, which was higher than that for any other year for which the records are available. The high-

est crude death rate from cancer occurred in the State of Vermont and was 101 per 100,000 population. Other States with high rates were Maine, 98.6; New Hampshire, 96.8; Massachusetts, 94.4, and Rhode Island, 88, while the lowest rates were shown for Montana, 40; Kentucky, 42; Washington, 46.1; Utah, 51.9, and North Carolina municipalities, 54.8. Among the cities having the highest rates were Albany, 122.8; Boston, 111.2; San Francisco, 110.6; Oakland, 105.3. Those with the lowest rates were Memphis, 51.9; Seattle, 57.4; Atlanta, 61.2; Detroit, 65.1, and Jersey City, 65.5.

Low Death Rate for New York.—The mortality statistics for the week ending September 13 show a rate of 11.50 per 1,000 population, the lowest death rate that the city has ever experienced with the exception of the week ending June 28, when the rate fell to 11.49. The death rate for the corresponding week of 1912 was 1.62. The death rate for the first thirty-seven weeks of 1913 is .26 lower than during the corresponding period of last year.

Government Investigation of the Friedmann Remedy.—The United States Public Health Service in a letter replying to an inquiry regarding the efficacy of the Friedmann treatment for tuberculosis states that the experiments which have been conducted by that department have not up to date been satisfactory. The formal report on the Government tests of the turtle bacilli is being prepared and is in accordance with the statements already given out to the effect that the bureau cannot give its recommendation to this form of treatment for tuberculosis.

The Drug Crusade in Jersey City.—A rumor to the effect that hundreds of young men in lower Jersey City had become addicted to the use of heroin and cocaine has led to an investigation by the Director of Public Safety. As a result four druggists and two clerks have been arrested on the charge of selling drugs illegally and have been held in $2,500 bail pending examination.

Personal.—Dr. E. S. McCain who has had charge of the quarantine work of the State Board of Health at Galveston has been transferred to Tampico, Mexico, in order to assume charge of the refugee camps at that port.

Dr. Louis W. Sambon of the British School of Tropical Medicine was the guest of the Medical Society of South Carolina on September 8. He addressed the society on the subject of pellagra and on his findings in regard to that disease in Charleston. He then went with several American scientists to Jamaica for the purpose of studying pellagra.

Examination of Candidates for Assistant Surgeon.—An examination is announced for the position of Assistant Surgeon in the Public Health Service at a salary of $2,000 a year with the privilege of examination for promotion with an increase of salary at the end of four years. Boards of commissioned medical officers will be convened to meet at the Bureau of Public Health Service, 3 B street, S.E., Washington, D. C., and at the Marine Hospitals of Boston, Mass., Chicago, Ill., St. Louis, Mo., New Orleans, La., and San Francisco, Cal., on Monday, October 20, 1913, at 10 o'clock A.M. for the purpose of examining candidates. Further information in regard to requirements and invitation to appear before the board of examiners may be obtained by addressing the Surgeon-General Public Health Service, Washington, D. C. The announcement states that successful candidates will receive early appointments.

Charitable Bequests.—*The will of Miss Emmalissa Purvis* leaves $1,000 to the Seney Hospital, Broklyn, N. Y.

By the will of Homer N. Lockwood the Auburn (N. Y.) Hospital receives $20,000 to be known as the Homer N. Lockwood Free Nurse Fund; the Women's Hospital and the Presbyterian Hospital of New York City each receives $5,000.

By the will of the late John L. Ringwalt of Philadelphia residuary bequests are made to Jefferson Medical College Hospital and the Chester County Hospital at West Chester, Pa.

By the will of the late Caroline C. Crosby the sum of $1,500 is bequeathed to the Methodist Hospital, but the bequest may be rendered void because it was made within thirty days of the death of the testator.

By the will of the late Judge Edward Harvey of Allentown, Pa., the sum of $50,000 is bequeathed to the Allentown Hospital to be used as an endowment fund for maintenance and also one-third of the residuary estate.

The Southern Minnesota Medical Association, which is to be held in Mankato, Minn., on December 2 and 3, has arranged for clinics to be conducted by Dr. Isaac Abt of Chicago, Dr. Robert H. Babcock of Chicago, Dr. James A. Herrick of Chicago, and Dr. Ludwig Hekteon of the University of Chicago.

The Negro Physicians State Medical Association of Louisiana at its meeting held in Shreveport on September 9 and 10 elected the following officers: *President,* Dr. W. H. Ennis of Bunkie; *Vice-President,* Dr. Thaddeus Taylor of New Orleans; *Secretary,* Dr. W. E. Shallowhorne of Baton Rouge; *Treasurer,* Dr. W. M. Wallace of Shreveport.

British Home Office Reports on Vivisection.—This report which follows an inspection of the conditions under which animal experimentation is conducted in England and Scotland states that everywhere the inspector found the animals suitably lodged and well cared for, and the licensees attentive to the requirements of the act, as well as to the conditions appended to their licenses by the Secretary of State. A graded series of licenses is issued by the Home Office specifying the requirements for different kinds of experiments. In all 83,599 experiments were performed during the year 1912, or 11,604 less than during 1911. An anesthetic was used in 5,043 cases, compared with 4,996 in the previous year. The report states that 24,870 experiments were carried out during the year by 24 licensees at eight institutions in the course of cancer investigation. Eighty-two licenses reported over 22,000 experiments, which were performed for Government departments, or public health authorities. During the year 1912 there were in all 598 persons who held licenses.

The National Medical Association, whose membership consists of colored physicians, druggists, and pharmacists, at its fifteenth annual meeting held in Nashville, Tenn., August 26-28, elected the following officers: *President,* Dr. A. M. Brown of Birmingham, Ala.: *Vice-Presidents,* Dr. J. M. G. Ramsey of Richmond, Va., and Dr. O. La Branch of New Orleans, La.; *Secretary,* Dr. W. G. Alexander of Orange, N. J.; *Treasurer,* Dr. J. R. Levy of Florence, S. C.

The New Hampshire Surgical Club held its autumn meeting at Portsmouth, N. H., on Septem-

ber 5, when the following officers were elected: *President*, Dr. F. E. Kittredge of Boston; *Vice-President*, Dr. Elmer H. Carleton of Hanover.

The Kentucky State Medical Association at its closing session on September 4 elected the following officers: *President*, Dr. J. W. Ellis of Masonville; *First Vice-President*, Dr. L. L. Neel of Warren County; *Second Vice-President*, Dr. M. McDowell of Cynthiana; *Secretary*, Dr. A. T. McCormack; *Treasurer*, elected for five years, Dr. W. B. McClure.

Permanent Commission of the Eighteenth International Congress of Medicine.—The following have been elected members of the permanent commission for the International Medical Congress, which is to be held in Munich in 1917.: *President*, Friedrich von Müller of Munich; *Vice-Presidents*, M Calman Muller of Budapest and Sir Thomas Barlow of London; *Secretary*, M. H. Berger of Amsterdam; *Assistant Secretary*, D. Ph. van der Haer of The Hague; *Member*, M. L. Dejace of Liege, who is president of the International Association of the Medical Press.

Obituary Notes.—Dr. Charles Lester Leonard of Philadelphia died of *x*-ray cancer at his summer home in Atlantic City on Tuesday of this week. He was born in 1861 and was graduated from the Medical Department of the University of Pennsylvania in 1889. Nine years ago a severe *x*-ray dermatitis developed on the right hand and when malignant degeneration appeared the hand was amputated. The disease, however, extended up the arm and this was removed at the shoulder at the beginning of the summer—too late, however, to save his life. Dr. Leonard was a member of the Polyclinic Hospital staff and was Professor of Roentgenology in the University of Pennsylvania.

Dr. Robert E. Moore of Brooklyn, N. Y., died at Saranac Lake on September 13, at the age of 34 years. He was graduated from Johns Hopkins University in 1896 and was a member of the New York State and Kings County Medical Societies. He was assistant surgeon to the Kings County and Bedford Street Hospitals.

Dr. Paul Gervais Robinson of St. Louis, Mo., a graduate of the Medical College of the State of South Carolina in 1856, died on August 23, aged 79 years. Dr. Robinson was a Civil War veteran and professor emeritus of the principles and practice of medicine in Washington University, St. Louis, Mo.

Dr. John Lochner of Jersey City, N. J., a graduate of New York University Medical School in 1871, died on September 5, aged 73 years. Dr. Lochner was medical examiner for the Jersey City Fire Department for twenty years, a member of the Jersey City Board of Health for nineteen years, and a member of the Hudson County Pathological Society.

Dr. Thomas Robinson of Washington, D. C., a graduate of the Georgetown University School of Medicine in 1876, and for forty years connected with the Treasury Department in Washington, died after a prolonged illness on August 24, aged 77 years.

Dr. E. V. Ezell of Angleton, Tex., a graduate of the Medical Department of the University of Louisville, Ky., in 1872, died on August 26, aged 60 years.

Surgeon Howard Smith of the United States Navy, a graduate of the University of Pennsylvania in 1871, died in the Naval Hospital at Norfolk on September 4, aged 65 years. He served on the interior coast defense and later on the *Michigan* during the Spanish-American War.

Dr. J. Howard Lever of Flushing, Long Island, N. Y., a graduate of the College of Physicians and Surgeons, N. Y., in 1869, died of cardiac disease recently at the age of 72 years.

Dr. George C. Laws died at Paulsboro, N. J., on September 5 at the age of 67 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1871. He was a veteran of the Civil War.

Dr. Frank J. Wagenseller of Selins Grove, Pa., died at the Samaritan Hospital, Philadelphia, on September 5, as the result of acute uremia following an operation, at the age of 58 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1875.

Dr. Amandus H. Fegley died at Spangsville, Pa., on September 4, of gangrene following infection of the foot, at the age of 70 years. He was graduated from Jefferson Medical College in the class of 1872.

Dr. Benjamin Franklin Severs died at Philadelphia on September 7 at the age of 58 years. He was graduated from the Long Island Medical College Hospital in the class of 1888.

Dr. Elwood Maulsby Corson died at Norristown, Pa., on September 7 at the age of 71 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863. He was a member of the Montgomery County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association. He served as surgeon in the U. S. Navy during the Civil War.

Dr. Charles H. Ballantine of Philadelphia died at Jefferson Hospital on September 8 at the age of 58 years. He was a graduate of the Philadelphia College of Pharmacy and of Jefferson Medical College in the class of 1882.

Dr. Charles A. Meeker of Newark, N. J., died at the Homeopathic Hospital in Newark following an operation for gallstones, aged 67 years. Dr. Meeker was one of the founders of the New Jersey State Dental Society, and Secretary of the State Board of Dental Examiners for eleven years; he was also a member of the Odontological Society of Manhattan, the New York Institute of Stomatology, and the American Academy of Dental Surgery.

Dr. James A. Coyne of Newark, N. J., a graduate of Jefferson Medical College in 1896, died at his summer home in Sterling, Mass., September 8, aged 40 years.

Dr. Walter M. Flemming of Mount Vernon, N. Y., a graduate of the Albany Medical College in 1862, died September 8, aged 75 years. Dr. Flemming practised medicine in New York City from 1869 to 1909.

Dr. Walter E. Russell of Walla Walla, Wash., a graduate of Hahnemann Medical College and Hospital, Chicago, in 1889, died of cancer after a lingering illness, on August 29, aged 55 years.

Dr. A. N. Fegley of Spangsville, Pa., a graduate of Jefferson Medical College in 1870, died September 4, aged 70 years.

Dr. Henry M. Emerick of Milton, Pa., a graduate of the Baltimore Medical College in 1880, died from acute indigestion on August 31, aged 59 years.

Dr. Philander S. Boyd of Florence, Ala., a graduate of the University of Tennessee, Nash-

ville, in 1888, died in New York City, where he had gone for treatment, on September 6, aged 63.

Dr. James O. Callahan of Muskogee, Okla., a graduate of the Missouri Medical College in 1888, died August 29, aged 53 years.

Dr. Thomas Edward Pickett of Maysville, Ky., died September 3 at the age of 72 years. He was graduated from the University of Pennsylvania in 1865, and was a life member of the British Association for the Advancement of Science, of the American Academy of Medicine, the American Association for the Advancement of Science, and the National Geographical Society. Dr. Pickett was one of the first men to introduce into this country the treatment of fractures by massage and mobilization. He was the author of the book, "The Quest for a Lost Race," which won him a membership in the Royal Society of Arts of England.

Dr. Nathan Jacobson of Syracuse, N. Y., died suddenly from a heart attack on September 16 shortly after arriving at the Syracuse Hospital for the purpose of attending to his usual duties. He was 56 years old. He was graduated from the Syracuse University College of Medicine in 1877. He was a member of the American Surgical Society, the American Medical Association, the New York Academy of Medicine. He was surgeon to St. Joseph's Hospital and consulting surgeon to the Hospital for Women and Children.

Dr. James M. Barr of Eufaula, Ala., a retired physician, died on September 8, at the age of 80 years.

Dr. Ephraim Wood Norwood of Spencer, Mass., a graduate of the Harvard Medical School in 1882, a member of the Medical Society of the State of Massachusetts and of the Worcester County and Brookfield Medical Societies, died suddenly on September 11, aged 65 years. He had served as medical examiner for his district for two terms of seven years each when he was appointed last year by Governor Eugene N. Foss to serve a third term.

Dr. John M. Smith of Williston, S. C., a graduate of the Medical College of the State of South Carolina in 1868, died September 12, aged 69 years.

Dr. John H. Howard of Lexington, Tenn., a practitioner of medicine for forty-eight years, died suddenly of pulmonary hemorrhage on September 7, aged 81 years.

Dr. Edwin Wilcox Bartlett of Milwaukee, a graduate of the University of Vermont College of Medicine in 1866, died after an illness of several months, on September 10, at the age of 74 years. He was a member of the American Ophthalmological and Otological Society, the American Medical Association, the Medical Society of the State of Wisconsin. He was Professor Emeritus of Ophthalmology and Otology in the Marquette University Medical Department, Milwaukee, Wis.

Dr. John R. Stivers of Brooklyn, N. Y., a graduate of the Long Island College Hospital in 1894, a member of the American Medical Association, the Medical Society of the State of New York, the Brooklyn Pathological Society, the Associated Physicians of Long Island, and the Long Island Medical Society, Visiting Physician to the Kings County Hospital, and Physician-in-Chief of the Samaritan Hospital, died September 18, aged 43 years.

Dr. George Batchelder Langmaid of East Greenwich, L. I., a graduate of the Boston University School of Medicine in 1876, a former practitioner of Melrose, Mass., died on September 15, aged 65 years.

Obituary.

JOHN GREEN CURTIS, M.D., LL.D.

NEW YORK.

Dr. John G. Curtis, brother of the late Dr. Edward Curtis, and for over twenty-five years professor of physiology at the College of Physicians and Surgeons, died at his summer home in Chatham, Mass., on September 20. Dr. Curtis was born in New York City, October 29, 1844, was graduated in arts from Harvard University in 1866, and in medicine from the College of Physicians and Surgeons of Columbia University in 1870. His leaning was at first toward surgery, and he was an attending surgeon to Bellevue Hospital from 1876 to 1880, and demonstrator of anatomy at Columbia from 1870 to 1875. In 1876 he was appointed assistant professor, and in 1883 full professor of physiology at the College of Physicians and Surgeons, succeeding the late Dr. John C. Dalton. In 1909 he retired with the title of emeritus professor of physiology. He was joint author of the American Text-book of Physiology, published in 1896.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE COMING SESSION—LONDON HOSPITAL EXTENSION — DENTAL EDUCATION, COMPLAINT, REGISTER, EXHIBITION — GOVERNMENT CLINICAL LABORATORY—SCHOOL OF TROPICAL MEDICINE—PREPARATIONS OF ERGOT—KING EDWARD'S FUND —OBITUARY.

London, September 5, 1913.

The shadow of the coming session is upon us, for the first of October continues to be the medical anniversary, when the schools reopen and new students make their entry. The hospital staffs and college teachers are specially interested, but more practitioners regard the first as a date on which to think of their old schools, and many to attend the dinner or other celebration of the occasion. The prospectuses are coming in apace, and each sets forth the attractions it can offer. The London Hospital is the largest and two prospectuses of its teaching organization lie before me, one of the "Medical College," the other of the "Dental School"—thick 8vo pamphlets of 112 and 65 pages respectively. The hospital itself dates from 1740 when as the "London Infirmary" its 136 beds occupied two houses but it soon became necessary to erect appropriate buildings and a Royal Charter was granted to the "Governors of the London Hospital" in 1758. From that time the growth has been continuous until now it contains 922 beds accommodating about 17,000 patients a year, while over 200,000 are relieved as out-patients annually. This great field for clinical study is cultivated by the staff and supplies special departments in every branch.

The Dental Department was remodeled and converted into a complete dental school a couple of years ago. Accordingly its third session will open on October 1 concurrently with the 129th session of the Medical College. How thoroughly well this dental school is equipped you may judge from its museum which contains besides the specimens for teaching others showing the dentition of all classes of animals. Students entering will find every facil-

ity for making themselves accomplished dentists and may at the same time qualify as members of the colleges or graduates of the university—a course strongly recommended even though they intend to restrict their future practice to dental surgery as ophthalmic surgeons and other specialists do. We have among us such distinguished practitioners of dentistry.

In contrast to them you may be surprised to hear of the existence of a small section of dentists who affect to consider their department as more than a branch, in fact as the greater part, if not the whole, of the healing art. The voice of these extremists made itself heard at the meeting of one association at Cambridge. One speaker complained that they were not properly supported by the doctors and wanted a public dental service. This set the ball rolling and another declared they were no specialty of surgery. The next went further by asserting roundly that doctors knew nothing about dentition, did not moreover know the difference between oral sepsis and pyorrhea. Another speaker was equally sure that the mouth was an unknown region to surgeons and a public dental service should follow the Insurance Act. I do not think any of those holding degrees or diplomas were present or would think it less honorable to belong to a branch of our profession than to an independent specialty.

The legal position is this: Any one on the Medical Register is entitled to practise the dental branch, but he cannot have his name on the *Dental* Register unless he holds a special diploma in that branch. As all the colleges of surgeons and most of the universities grant such diplomas, the dentists have no room for the complaint that their art is neglected.

An International Dental Exhibition has been held this week. It was organized by the Incorporated Society—not the one where the complaints were made—and it is said to have brought together the most complete collection of inventions connected with dentistry ever shown. All practitioners were invited to view it but the lay public were not admitted.

The government chemist's report on the work of his laboratory has appeared as a Parliamentary paper. Besides the usual chemical work for the government departments and public bodies investigations for the home office on lead compounds in paint, celluloid, milk powders, and non-alcoholic beverages have been made. The samples examined have increased during the year—354,759 analyses were made. For checking dilution and adulteration 9,453 samples of beer were taken from 2,398 retailers. It was found diluted in 581 to the extent of not more, as a rule, than 3 to 36 per cent., but occasionally as much as 12 to 36 per cent. The manufacture of sugar from beet root was again commenced after a lapse of some forty years. The process was under the observation of the revenue authorities and analyses were made of all stages. The heavy duty on saccharin which has 500 times the sweetening power of sugar renders smuggling such a temptation that it is said to be searched for in all likely places and 526 samples were examined for it. Other analyses were called for in relation to cider, wines, spirits, tea, tobacco, etc., for the customs and excise, as well as articles of food for the navy and testing others for the board of agriculture and other government departments.

Important additions have been made to the buildings of the London School of Tropical Medicine. The new laboratory is continuous with the former one making up a square and setting free space for special preparation and investigation rooms. Resident accommodation is provided chiefly in response to a wish expressed in India and other dominions from which a demand has also been made for a course in tropical sanitation and hygiene. An eight weeks' course of laboratory study of this kind has been arranged and will include bacteriology. Students can be prepared for examinations and those who have passed such can take out extra courses which would give them advantages as candidates for positions in tropical countries where good salaries are to be obtained with great opportunities for original investigations connected with tropical medicine and hygiene.

The B. P. preparations of ergot have long been considered as unsatisfactory—so much so that numerous proprietary articles have largely displaced them. The ergots of other grasses have to some extent been substituted and it is admitted that ergot of wheat is more active while one from a New Zealand plant is much more potent. The active principles also, ergotoxine, ergamine, and tyramine have been tried; they have the advantage of being obtainable in crystals. Messrs. Carr & Dale brought the subject before the late Pharmaceutical Conference in a paper pointing out the deficiencies of the B. P. preparations and offering definite suggestions. The extract, generally regarded as the most uncertain, they would reject, though if such a form were thought necessary they would make it with alcohol 60 per cent. and 2 per cent. citric acid. Instead of the liquid extract they recommend that of the U. S. Pharmacopeia. For the injection they would employ salts of the active crystals. The infusion would not be required if the U. S. fluid extract were employed, nor would the tincture, which is a very unstable preparation, perhaps due to its containing ammonia.

The statistical report of King Edward's Hospital Fund for 1912 was issued yesterday. It deals with 109 hospitals which provide together 9,223 beds in daily occupation during the year; the total number of in-patients admitted being 134,647 while 1,529,197 out-patients were seen. The ordinary expenditure amounted to £1,038,791. This, of course, excludes all capital expenditure and interest on borrowed money. The total income would not, by a large amount, have sufficed to meet the year's working expenses, without the grants made by King Edward's Fund and the Metropolitan Sunday and Saturday Funds. The increased cost noticed in 1911 has continued in 1912 amounting now to £21,800. Before 1911 there had been for several years a tendency to decrease. No doubt there has been a rise in prices but not enough to account for the present increase. These statistics will assist hospital managers, contributors, and all interested in comparing any particular hospital with others, as to cost per bed for in or out patient, etc. It makes available a mass of material supplied by each hospital for the assistance of all in their efforts for economy.

Inspector-General of Hospitals and Fleets, Sir Duncan McCormick Hilston, M.D., K.C.B., Hon. Physician to the King, whose death occurred on August 28, at the age of 76, saw service in New Zealand 1863-4, was wounded and was mentioned in dispatches and received the medal. In 1867-8 he was in the Abyssinian War for which also he received the medal. At one time he had charge of Hasler Hospital being the inspector-general. He

received the higher inspectorate in 1892 and retired in 1897.

Col. Andrew Clark (A. M. S. T.), F.R.C.S., Consulting-Surgeon to Middlesex Hospital, late surgeon and lecturer on surgery, died on August 29, æt. 66. He qualified in 1868-9, was made D.Sc. (Hon.) of Oxford, 1873, and took F.R.C.S. the same year. He filled many offices at the Middlesex and became president of its medical society. He wrote its Surgical Reports 1872-3-4, gave the ambulance lectures 1888, and edited the fourth edition of Fairlie Clarke's "Manual of Surgery." He held the Volunteer decoration and contributed to the *Path. Trans.* and societies and journals. He had been examiner at the Apothecaries' Society and consultant to several institutions.

Progress of Medical Science.

Boston Medical and Surgical Journal.

September 11, 1913.

1. Gonococcus Vaccines and Glycerine Extracts of the Gonococcus in the Diagnosis of Gonorrheal Infections. G. C. Shattuck and W. S. Whittemore.
2. The Pathological Lesion of Whooping Cough. F. B. Mallory.
3. Note on Adductor Response to Homolateral and Contralateral Stimulation. A. Myerson.
4. Fibroma of the Ovary Weighing Thirty-five Pounds. Operation. Recovery. R. S. Titus.
5. Tests for Renal Function Based Upon the Selective Excretory Activities of the Kidneys. R. Fitz.
6. A Case of Anthrax. G. A. Buckley.

1. **Gonococcus Vaccines and the Diagnosis of Gonorrhea.**—G. C. Shattuck and W. S. Whittemore conclude that the reactions thus far observed after injections of gonococcus vaccine have not been clearly specific for gonorrheal infection. The reactions seem to show a selective action in some types of gonorrheal disease. Local reactions after injections are common in non-gonorrheal cases. They are not valuable for the diagnosis of gonorrhea or for the demonstration of its cure. Focal reactions are seen frequently in active gonorrheal arthritis and salpingitis; but, whereas they have been observed in cases showing no other evidence of gonorrhea, their diagnostic value is small. A general reaction is seldom noticeable, and it may be easily simulated by slight symptoms due to other causes. it has, *per se*, no diagnostic value. Gonococcus vaccine autolyses rapidly, and thus undergoes changes little known. A concentrated vaccine used by the authors showed no superiority for diagnostic tests. It produced in gonorrheal and in control cases a local lesion like that of a chemical irritant. The authors believe that autolysis may have been a factor in producing the supposedly irritating properties of their vaccine; that the changes in the vaccine may have prevented it from producing a specific reaction; and that the unsatisfactory therapeutic effects of gonococcus vacine may, perhaps, be traceable to autolysis. Glycerine extracts of the gonococcus inoculated by the method of von Pirquet caused, in a few cases, the formation of peculiar papules which may have represented a specific reaction. Most of the cases showed no definite reaction. Although the authors' tests were negative in the main, and although the work of others using similar methods has yielded unsatisfactory results for diagnosis, the authors believe that failures serve as guideposts to progress, and that present knowledge justifies the hope that a valuable diagnostic test for gonorrheal infection may yet be devised through improved methods of preparing vaccines or extracts of the gonococcus.

2. **The Pathology of Whooping Cough.**—F. B. Mallory has observed in cases dying of whooping cough the presence of minute organisms packed in large numbers between the cilia of the epithelial cells lining the trachea. Better sections and stains showed the organisms to be minute bacilli. They were present in great numbers, dozens to a hundred or more, over the surface of each cell. The action of the *Bacillus pertussis* seems to be largely mechanical. It interferes with the normal movements of the cilia and therefore furnishes a continual irritation which excites the coughing. The organism also secretes a mild toxin as is indicated in three ways by a slight inflammatory exudation, by a lymphocytosis, and by the production of a specific antibody. The finding of this particular lesion naturally suggested experimental work. The author first obtained sputum from acute cases of whooping cough and inoculated it into the trachea of a puppy and of a rabbit. Later the animals were killed and the respiratory tract was studied microscopically. Organisms identical in every way with those found in whooping cough were present between the cilia in the trachea and bronchi of both animals.

3. **Adductor Response to Homolateral and Contralateral Stimulation.**—A. Myerson points out that the adductor reflexes, whether homolateral or contralateral, are more independent of the site of stimulation than any of the tendon reflexes. Occasionally a knee jerk can be obtained from the sole of the foot or upper partitions adjacent to the patella. The ankle jerk can also at times be elicited from the sole of the foot, a phenomenon first observed, so far; but, in a case reported by the author, both the contralateral and homolateral adductor reflexes were obtained from the anterior superior spine, from the patella tendon, from the internal condyle, from the sole of the foot, from the Achilles tendon, etc. The author concludes that the homolateral adductors either depend for their elicitation upon or are intimately related with the existence of the knee jerk on that side. The knee jerk may be present without these reflexes and often is so present, but the reverse does not obtain. In the author's case, with the left ankle jerk absent, all the left adductors were absent. In the same way the contralateral adductors are intimately related to the existence of the knee jerk opposite to the side of stimulation, but are in no way dependent on the knee jerk of the side of stimulation.

2. **Results with Piorkowsky's Turtle Tuberculin.**—W. J. Beattie and E. E. Myers report their results with the use of this preparation. They state that the most suitable cases are the incipient pulmonary, glandular, laryngeal, and joint cases. In glandular cases the most striking beneficial effect of turtle tuberculin is observed in glandular tuberculosis. Improvement is noticed after three weekly injections have been made. The glands gradually become smaller and, where there is a discharging sinus, the secretion progressively diminishes, the opening becomes smaller, the sinus finally closes up, and the temperature gradually returns to normal. The patient gains in weight, his appetite improves, and a feeling of buoyancy replaces that of languor and lassitude. In the case of joint tuberculosis after about four weeks there is a noticeable diminution of the swelling about the joints, the pain diminishes or disappears, and the amount

of motion is increased from five to ten degrees. In pulmonary tuberculosis in about six weeks after beginning treatment the patient's general condition improves. His cough becomes less, and his sputum diminishes and becomes more mucoid in character. The pains in the chest disappear, and the night sweats become lessened and gradually disappear. If a patient has a localized bronchitis the râles gradually disappear. If there is an area of consolidation this is occasionally noticed about the end of the eighth week. In laryngeal tuberculosis the ulcerations slowly but progressively diminish and soon heal. The treatment is usually continued until all objective and subjective symptoms disappear, which is generally in from six to nine months. The duration of the course of treatment varies with the stage of the disease and the type of the case. Glandular and joint cases usually respond in six months.

9. **Cerebrospinal Meningitis in New York City During Fifty Years.**—M. L. Ogan notes that outbreaks of the disease have not been very frequent, and show a remarkable periodicity, occurring about every ten years. In 1872, 1881, 1893, and 1904-5 the death rate per 10,000 of population reached 8.7, 4, 2.7, and 5.4. In the year after the outbreak the rate was above the average, but during the remaining intervening years it was very low. Thus, from the sixties up to 1872 it was less than one-half of one per 10,000 annually, though steadily advancing. From then it rose to 1.5 in intervening years, then showed a tendency to decline, until the advent of lumbar puncture and bacteriological diagnosis, when the interim average fell at once below one per 10,000, due to the exclusion of many tuberculous and other cases from the statistics. The effects of the great outbreak of 1872-3 are felt to the present time. These combined years yielded a death rate of 10.5. Never since that time has the rate come down to the one-fourth of one per 10,000 which had characterized several preceding years, even with the aid of more exclusive diagnosis and serum treatment. Each of the two succeeding decennial outbreaks showed a marked tendency to a decline in severity, and the interval annual rate also was slowly falling until the remarkable outbreak of 1904-5. This, the fourth epidemic in a half century, was the severest of all, showing a death rate for the two years of 10.9, which is even higher than that of 1872. Eight years have passed since that time, and the death rate has fallen from 1.02, in 1906, to 0.36, in 1912. The mortality in serum treated cases is reduced at least one-half from the old rate of seventy to seventy-five per cent. Flexner's analysis of a world wide series of 1,294 cases shows a fatality of only 30.9 per cent.

1. **Streptococcus Sore Throat.**—J. A. Capps reviews the history of the epidemics of streptococcus sore throat at Boston, Baltimore, and Chicago that have occurred within the past two years. About 1,400 persons were stricken in the Boston outbreak; in Baltimore, about 1,000, and in Chicago, it is estimated, over 10,000, though 1,271 were interviewed. In all three cities a peculiar type of hemolytic capsulated streptococcus was secured from throat cultures or from the peritoneal exudate of fatal cases. Those from each outbreak were compared and found practically identical. The disease occurred during the winter and spring months and its onset was explosive, often affecting several members of the same family at once. The clinical symptoms were identical in the three epidemics. Intense hyperemia, with or without a grayish exudate, was the usual picture, and enlargement of the cervical lymph nodes, sometimes with suppuration, was characteristic. Extreme prostration and a tendency to relapse were emphasized by most observers. The complications were strikingly similar in all three epidemics. Otitis media, peritonsillar abscess, erysipelas, or some other skin eruption were common sequelæ. Arthritis, endocarditis, and myocarditis occurred in many cases. Pleurisy and pneumonia often ushered in a fatal septicemia, but the most dangerous and remarkable complication was peritonitis, which caused a number of deaths. The infection was traced definitely to a single milk supply in each city, though secondary contact cases also occurred. In the Boston epidemic the actual primary infection was attributed by Winslow to a human carrier. In the Chicago epidemic the history of a sore throat epidemic among the workers in the milk supply was also established. Human carriers, however, do not fully explain these epidemics as well as does mastitis in the cow, which may itself originate by transmission of human streptococcus from the milker.

6. **Chronic Adherent Pericarditis.**—W. H. Smith concludes from a study of his cases that adherent pericarditis may be impossible of diagnosis in cases unassociated with cardiac symptoms, cardiac enlargement, or murmurs. The diagnosis under such conditions is unimportant, as in this type of the disease it probably contributes but little to the disability of the patient. A second type in young adults, with a previous rheumatic history, with associated endocarditis, is serious. Adhesive pericarditis is overlooked because the coincident endocarditis appears in the foreground. Adhesive pericarditis should always be thought of in a young adult whenever rheumatism followed by endocarditis appears in the history, and especially considered when the cardiac failure is more marked or the cardiac enlargement more

extensive than the endocardial damage seems to warrant. More careful records should be made of the presence or absence of cardiac dilatation in cases of acute rheumatism without endocarditis or pericarditis.

9. **Sanatorium Treatment of Tuberculous Gravidæ, Puerperæ, and Their Children.**—C. S. Bacon states that there are 32,000 tuberculous women pregnant each year in the United States, and about a third of them die within a year of labor. Of 10,000 children under five years old who die of tuberculosis each year, three-fourths are born of tuberculous mothers. Besides this mortality there is also an increase of infection among the attendants, relatives, and associates, and this factor has not been sufficiently recognized in the past. The proper obstetrical management of these cases can be carried out in a private house only with considerable difficulty and probably not more than 10 per cent. of the cases are ideally managed at their homes. Maternity hospitals do not care to take tuberculous cases and the conduct of the latter part of pregnancy and a long puerperium cannot well be provided. Hence the necessity of a maternity department in the tuberculosis sanatorium, and Bacon thinks that three-fourths or nine-tenths of the cases should be cared for in such. Up to the present time there has been no provision for such patients in this country or in Europe, and this is probably in part due to the fact that no special emphasis has been laid on this feature of the tuberculosis problem and in part to the difficulty of making such provisions. It is with the object of calling attention to this need that his paper is written, and he gives an account of the provisions being made in the Chicago Municipal Tuberculosis sanatorium now being constructed. In this there are accommodations provided for gravidæ, a room for confinements, and departments for caring for children. The outline is given as a contribution to the solution of the problem and to stimulate discussion. Later he hopes to be able to describe its work and compare it with other like institutions.

12. **The Emetic Action of Digitalis.**—C. Eggleston reports the results of a study of the emetic action of digitalis, so frequently observed with the use of this drug in cardiac disease. Experiments on animals indicate that the emesis is due to a direct action on the bulbar centers by absorption and the characteristic phenomena occur in dogs after removal of the gastrointestinal tract. While the same methods cannot be employed on man, it was thought that if careful clinical observations in cases of heart disease showed that nausea and emesis were dependent on absorption of the drug, it would support the view of the central action of digitalis in therapeutic doses. There is no valid evidence, either experimental or clinical, that the emesis after digitalis administration is due to gastric irritation, but much and strong evidence to the contrary, and from both clinical and experimental findings the conclusion that they are due to a direct action on the vomiting center is a logical necessity. The author concludes that it is irrational to seek to avoid these symptoms by resort to another preparation or another channel of administration. Apparent success from such methods is due either to a weaker emetic action or less absorption of the new preparation, or the new channel is one in which absorption has been less complete.

13. **Physiology of the Pylorus, Pilleus Ventriculi, and Duodenum.**—L. G. Cole calls attention to his findings in the first inch and a quarter of the pylorus which differs materially from those of the descending and horizontal portions, and for which he proposes the name pilleus ventriculi or cap of the stomach. The differences have been noticed by others, but the author's claims to be the first to specially recognize it as belonging more to the stomach than to the intestine, are made prominent. Its roentgenographic appearance is of value in the recognition of gastroduodenal lesions. It may be spasmodically contracted and variations resembling pathological deformities may occur. Its function is that of a reservoir. It receives the acid chyme propelled through the pylorus and it is probable that the finishing touches of gastric digestion are done here. It is separated from the pars pylorica by a space of one-eighth to one-quarter inch occupied by the pyloric sphincter. The author discusses certain questions relating to the function of the sphincter, and says that from a careful study of more than 12,000 serial roentgenograms in about 500 cases he has not been able to detect the rhythmic contraction which has been described. A study of these pictures shows that during the systole of every gastric cycle the pylorus is open and a small amount of the liquid chyme is propelled into the reservoir cap. This occupies about seven-tenths of the cycle. The other three-tenths is occupied by the diastole in which the peristaltic contraction of the stomach reaches the sphincter and closes it so that the chyme is prevented from dropping back into the stomach. The emptying of the cap, he concludes, is effected through duodenal peristalsis. The motor phenomena of the pylorus, pilleus ventriculi, or cap, and duodenum can be demonstrated in all human stomachs having a moderately active peristalsis.

22. **The Rôle of the Prostate and Seminal Vesicles in Toxemia.**—By H. Young. (See MEDICAL RECORD, July 5, 1913, page 37.)

23. **Therapeutic Pneumothorax.**—K. Dunham and C. S. Rockhill report twenty cases in which artificial pneumothorax was used as a palliative measure in tuberculous patients. The most important items for success in this treatment are local anesthesia, perfected apparatus, accurate technique, careful asepsis, the ability of the one lung to collapse and of the other to carry the double burden, and the accessibility of the patient for the necessary refillings. The careful selection of cases often determines success, and the Roentgen rays prove that refilling should be frequent and the gas-pressure slight, the amount of gas injected being just sufficient to keep the lung collapsed and no more. If the negative pressure is raised to zero, this is more than enough. The possible dangers are heart displacement causing derangement of blood-supply or kink in the vessels, which, like a break in the mediastinum, might result from too great strain; gas embolism, which can hardly be insured against, but can be largely guarded against by careful watching and can then be properly treated; infections of the pleural cavity; emphysema, which is more an inconvenience than a danger; and abnormal conditions which have been avoided by never giving an injection during the menstrual period or after a debauch. The authors' real advance beyond their predecessors has been in the constant use of stereoscopic roentgenograms to determine the extent of the lung collapse, to avoid pressure on the heart and mediastinum, to exclude pleural effusion, and to safeguard the unfilled side.

25. **The Administration of Alkaloids Before Anesthesia.**—Isabella C. Herb concludes that the administration of morphine, scopolamine, and atropine before general anesthesia has certain advantages, but these advantages are not sufficient to counterbalance the risks attendant on their employment. The loss of the pupillary reflex is a serious handicap, as nothing else indicates so unerringly the degree of narcosis. That the danger from ether, chloroform, or nitrous oxide is diminished is contrary to the evidence at hand. The alkaloids should not be employed when untrained, inexperienced anesthetists are in charge, as the anesthetic is rendered more complicated and extra skill and judgment are required. The routine use of cer-

tain fixed doses before every anesthetic regardless of the patient's condition should be discouraged. The employment of alkaloids has a distinct field of usefulness before local analgesia.

26. **Nitrous Oxide and Oxygen Anesthesia.**—By H. G. Sloan. (See MEDICAL RECORD, July 5, 1913, page 38.)

27. **Intratracheal Insufflation Anesthesia.**—C. H. Peck notes that intratracheal insufflation, administered with accurate control of the strength and amount of ether vapor, is a new principle in anesthesia which in certain classes of cases has many advantages over other methods. The difficulty of intubating and the necessity of inducing full surgical anesthesia before this can be accomplished makes this method unsuitable for many short, simple operations. Its use should be restricted to the cases in which it has special advantages. It is absolutely safe both as to administration and freedom from deleterious after effects if a proper apparatus is used and the simple precautions mentioned in detail are observed. It is an ideal method of differential pressure for operations involving the opening of one or both pleural cavities, greatly reducing the danger of intrathoracic operations. It greatly lessens operative shock through the absolute relief of strain on the respiratory apparatus and coincident freedom from strain on the circulatory apparatus and the central nervous system, and from the even, advantageous degree of anesthesia maintained. This is especially evident in aged patients, in those cachectic from malignant disease or anemia, and debilitated from other causes. The disparagement of ether as an anesthetic as compared to nitrous oxide, so popular of late among the advocates of the latter, is based on observations of faulty methods of ether administration rather than the inherent toxic effect of the drug itself. The wide margin of safety with ether has so long permitted abuse with this drug that faulty technique has been assumed by its opponents as customary in its administration. It prevents aspiration of mucous or saliva, vomitus, blood or other foreign matter into the trachea; simplifying and decreasing the danger of operations on the tongue, jaws, mouth, nose, or pharynx; preventing aspiration pneumonia, and practically eliminating the necessity of preliminary tracheotomy in such cases. It is especially useful in operations about the head and neck. The anesthetist is out of the way; the operative field is easily kept sterile and obstruction of the upper air-passages is absolutely prevented. The same may be said of operations on the kidney, the spine, and in awkward positions in general. The degree of anesthesia is under perfect control. Overetherization is impossible at or below 21 per cent. by weight of ether vapor. Insufflation of pure air for the last few moments of the operation hastens the recovery of consciousness and minimizes the after-effects.

28. **Local Anesthesia.**—By J. F. Mitchell. (See MEDICAL RECORD, July 5, 1913, page 38.)

30. **General Anesthesia in the Surgery of Childhood.**—By W. C. Woolsey. (See MEDICAL RECORD, June 28, 1913, page 1189.)

33. **Syphilis and the Nervous System.**—Joseph Collins points out that the most serious of the organic diseases of the nervous system are syphilitic; myelitis and cerebral and spinal endarteritis may occur during the first months after the infection, and tabes and general paresis, which are exclusively due to syphilis, often display their initial symptoms within five years. The conceptions of parasyphilis and metasyphilis have been a drawback in treatment; now it is known that syphilis is syphilis, no matter in what form it is encountered. The negative Wassermann reaction does not, however, necessarily exclude syphilis. The treatment by the rank and file of the profession of the present day is the old one of mercury by the mouth for a year, mixed treatment for another year, and after that the iodides alone. The author does not say that this is practised by all, but for one case properly treated and controlled by the Wassermann reaction twenty are treated in the old fashioned way. Syphilis is not a local disease and its primary manifestation is not by any means necessarily the classical chancre. The spirochete may enter the body in various ways and the sooner one can get at it with salvarsan the better. Hence it is dangerous to wait for secondary manifestations, and it is dangerous to trust to mercury by the mouth. It is more than likely that there are definite strains or varieties of the spirochete and that one of these may elect the nervous system as others do the skin. This cannot be proved at present, but it is scarcely a coincidence that so many of the author's syphilitic patients had a history of light primary attacks. In nearly 1,000 administrations of salvarsan the author has seen serious consequences in only one case, an apparent myelitis which recovered in four months, and was probably edema rather than inflammation. Severe toxic effects have been observed in four cases similar to acute arsenical poisoning, but readily yielding under treatment. Salvarsan is more efficient than neosalvarsan, though the latter has some advantages in administration its effects are not as good.

2. **Remedies for Pain and Sleeplessness.**—R. Jones notes that tea and coffee drinking as well as the excessive use of alcohol and the various drug habits are frequent causes of sleeplessness. Intestinal autointoxication may be associated with sleeplessness. The latter may also be caused by beginning arteriosclerosis, in which case erythrol tetranitrate acts better than any sedative. Indirect remedies for sleeplessness associated with increased arterial tension are podophyllin, ¼ grain; extract of colocynth, 2 grains; aloes, 2 grains, and etaterium, 1/10 grain. By adding tone to the cerebral arterioles digitalis may act as a cerebral sedative, especially in the wakefulness of delirium tremens. When strychnine is used its effect is best kept up by alternating it with the tincture of nux vomica. Of the direct sedatives opium is at the head of the list. The conium preparations are generally unreliable. Chloral hydrate has the disadvantage of weakening and depressing the heart. Paraldehyde is a safe hypnotic in dose of one-half to two drams. Of all the sedatives the bromides are the most valuable to the nerve centers. They are best given in single large doses. Cannabis indica is useful in sleeplessness associated with migraine, asthma or uterine spasm. Sulphonal is a strong neuronic poison. It should be used only for the sleeplessness of chronic cases. Urethane, given in five-grain doses, is a safe and useful hypnotic.

5. **The Effect of the Ductless Glands upon Development.**—Hastings Gilford discusses the inhibition or reenforcement of such correlations of the body as are carried on through the medium of chemical secretions or hormones. There are certain local adjustments that are independent of the nervous system and of the ductless glands. In considering the problem of the disorders of these organs and the light they throw upon their normal action one is greatly aided by the advanced state of one's knowledge of the thyroid gland. This shows that the inaction of a gland at one stage of development may produce results which superficially differ from those in another stage of development, and that those due to defective action are by no means always contrary to those due to ex-

cessive action. Thus the infantilism, dwarfism, and sexual stagnation of cretinism cannot be contrasted with any premature senile decay, gigantism, or sexual exaltation in Graves' disease. Neither is there any orbital change in cretinism opposed to the bulging eyes of Graves' disease. It seems clear that the part allotted to the thyroid in the complex working of the ductless gland system is to stimulate the metabolism of the whole body. A gland in certain respects in inhibitory relations with the thyroid gland is the thymus, which is regarded as a lymphoid structure and part of the lymphatic system. There is a striking contrast between the human being in infancy and childhood, when lymph tissue is at its highest development, and the condition met with in Graves' disease. This contrast is accentuated in lymphatism, where the special type qualities of the infant are magnified. Destruction of large tracts of the lymphatic system by degeneration, as in Hodgkin's disease, gives rise to a syndrome in which extreme emaciation and debility and catabolic excess may be contrasted with the stolid fatness of lymphatism and with its pallor and increased muscular growth. By studying these extremes one may arrive at some sort of conclusion, however hazy, as to the normal action of the glands in question. One finds that by virtue of their secretions, or in some more cryptic manner, they preside over certain correlations of the body. These correlations are by no means rigid, but are, indeed, exceedingly variable, and this variability is most apt to be shown when circumstances are abnormal. The adjusting mechanism of development is not only flexible, but is more or less reciprocal, so that a ductless gland both influences development and is itself influenced by the changes of general development. In the harmony which is produced by the concerted action of the ductless glands there is reason to suppose that the leading part is played by the thyroid. This supplies a stimulus for the metabolism of the body as a whole. During infancy and childhood, when it is most important that the fires of metabolism should be controlled, the influence of the thyroid is checked by the thymus gland, by the lymphatic system in general, and perhaps by the pineal gland. These also bring about that delay of sexual activity which is so essential to the proper maturation and stability of the somatic faculties. Probably the first to break through this cordon of conservative influences is the adrenal system which awakens the dormant sexual organs and hastens the growth of the muscular and skeletal systems. At about the same time the skeletal system is still further stimulated by a secretion from the pituitary gland. This secretion quickens the development of every organ in the body, including the sex organs. These latter now ripen apace, and assisted by the combined action of the ductless glands, some animating, others restraining, carry the development of the body in waves and tides to its flood.

6. Military Experiences with Traumatic Aneurysms.—V. Soubbotitch reports the results obtained in the treatment of traumatic aneurysms in the military hospitals of Servia in the recent wars. Operations were performed upon 60 arteries and 17 veins. The femoral artery was tied 22 times and sutured 11 times. These cases occurred among 20,000 wounded. Many aneurysms are cured by non-operative treatment, especially by well applied digital pressure, but these proceedings are difficult to carry out in military hospitals in time of war. Where the conditions make it possible non-operative treatment should be attempted. The author has tried injections of gelatin on several occasions, but only with transitory success. If hemorrhage threatens, if the swelling increases, if the pain is severe, if there appears no tendency toward retrogression, then it is certainly better to operate than to wait. Arteriovenous aneurysms should be operated upon, as they offer small prospect of spontaneous cure, although they often remain stationary for a long time and cause relatively little trouble. A certain amount of preliminary treatment is useful. It is especially desirable, when there is much swelling, that the limb should be elevated for a time in order to reduce the swelling, if the conditions permit of this. If operation is undertaken early, within a few days of the injury, the walls of the vessel will probably be found soft and friable, and the stitches will tear out easily. On the other hand, with later operations, three to four weeks after the injury, cicatricial changes are often found which render the dissection to a certain extent difficult. If there is extensive extravasation of blood into the surrounding tissues the hematomata should always be removed. Simple ligation of the afferent artery, without removal of the clots, may in certain cases cut off the circulation completely and thus produce gangrene. In some cases local anesthesia is sufficient. The localization is often more easy if the operation is performed without the use of an Esmarch bandage. The Servian army surgeons did most of their operations without it. Nevertheless, when this is possible, the bandage may be laid loosely round the limb in readiness for use if required. Perhaps the damage to the vessels is also less if Esmarch's bandage be not employed. If violent hemorrhage suddenly occurs, as it often does while the dissection of the vessels is being carried out, it is not always easy to bring the bleeding points quickly into view. It is frequently possible with surprising rapidity to feel and to close with the finger the hole in the vessel from which the blood is flowing and which is frequently quite large.

1. The Diagnosis of Pulmonary Tuberculosis.—C. Riviere reminds one that phthisis is a disease of intermittent course, that the real beginning is often passed over as an influenza or a "chill," and that it has generally advanced to quite diagnosable stages by the time the patient has discovered his symptoms. This is true, as a rule, even in cases of hemoptoic onset; even here signs are generally discoverable to skilled examination. One should devote all the attention one can to ordinary physical signs, especially to light percussion, and after this to auscultation. The modern methods cannot in any way take the place of physical examination, though they are most valuable aids to it. One should not, also, neglect the temperature chart, nor yet the evidence of symptoms. One should also study carefully the value of the evidence to be derived from modern methods. Blind reliance should not be placed on any of them, any more than it should be on any single physical sign. Most of these modern methods give valuable information, but this must be weighed against other information from other sources before judgment is given. If this is done, and the other methods, under modern improvements, are not put aside, it may be said that we have made considerable strides in the diagnosis of phthisis in recent years. It is, indeed, only here and there that a case is met in which skilled examination is not able to decide the matter, and that fairly rapidly, one way or the other.

4. Salvarsan in Congenital Syphilis.—J. W. Simpson and L. Thatcher conclude that salvarsan is a potent remedy, and with proper dosage and technique can be used with safety in the case of the youngest child. In very severe cases, however, such as those with pemphigus, extreme wasting, etc., the dose should be reduced from

0.01 gram to perhaps half that amount. In three of the authors' most severe cases death ensued within sixty hours, and they think that a smaller dose, repeated afterward if necessary, would have been safer. In comparison with mercury, salvarsan gives much better results, especially in the severer cases. After giving an injection it is wise to continue the mercurial treatment, as a combination of the two seems to be more efficacious. Some of the authors' cases, however, which did not attend again for three or four months, had done well with salvarsan alone. In all the older children mercury and iodide had been previously given, with very slow improvement (especially in eye cases). After salvarsan was given improvement was much more rapid, but it is always advisable to carry on the mercury and iodide treatment also after the injection. In doubtful cases of congenital syphilis it is better to take the blood from the mother for a Wassermann reaction than to submit a weakly infant to such a procedure.

6. **Acute Pancreatitis.**—A. J. Evans points out that acute hemorrhagic pancreatitis, gangrenous pancreatitis, and purulent pancreatitis are simply phases of the same disease. The symptoms are at first vague in the early stages. There is often gastric uneasiness, flatulence, obstinate constipation, and persistent vomiting. After some hours—sometimes several days—the patient is struck down by agonizing, unbearable pain in the epigastric region, often shooting toward the back. This is followed by vomiting and collapse. The pain is continuous, with periods of paroxysmal increase, and it may be so intense as to cause the patient to faint. There is also acute tenderness of the upper abdomen, especially so in the middle line. The pulse becomes rapid and thready, and assumes the abdominal type. The temperature is usually normal or subnormal, but as inflammation increases it may become irregular. In two of the author's three cases there was marked cyanosis, in striking contrast to the pale, pinched aspect of ordinary peritonitis. Constipation is a marked feature, so much so that this condition has been mistaken for intestinal obstruction. Delirium is very constant, and was particularly marked in the author's third case, alternating with perfect mental clearness. Jaundice may be present. Its presence and its intensity are entirely dependent upon whether there is obstruction in the bile passages or not. Sugar is rarely found in the urine, although it was present in the author's case. If the disease has progressed for some days a definite mass can be felt in the epigastric region; it is well defined, circumscribed, and limited to the upper abdomen. The treatment is wholly surgical—immediate laparotomy, with exposure of the pancreas, and its free drainage.

Cystinuria.—Fromherz has collected notes from the recent literature of this subject. Cystin is an amino acid and is present in most albumins, constituting the sulphur complex of the molecule. It is obtained most readily from horn shavings and hair. Chemically it is cystein disulphide. In rare cases it is found in the urine in hexagonal crystals, and its presence leads naturally to calculus formation. Urine cystin is identical with the cystin split off artificially from albumin. In severe cystinuria cystin crystals may be found in various organs and even may be universally distributed throughout the body. It is disputed whether or not a trace of cystin in the urine is physiological or not. If a normal subject ingest cystin it is completely burned in the body when given beneath certain limits, the sulphur for the most part reappearing in the urinary sulphates. There has been much dispute as to whether or not cystin may change to taurin. When the organism cannot oxidize cystin we should find associated a general insufficiency in attacking all of the other amino acids. We sometimes see in certain urines, along with cystin, leucin and tyrosin. As the fate of the amino acids in the body is normally transformation by various steps into urea, their appearance in the urine indicates an interference with this process. In theory diamines should also be found in cystinuria. This has in fact been witnessed by observers who found putrescin and cadaverin penta- and tetramethylendiamin. It is quite probable that alkaptonuria represents an allied condition. The interference with normal metabolism present under all these circumstances seems to have little bearing on the general health, aside of course from the formation of cystin concrements in the urine. Cystinuria no doubt sometimes accompanies rheumatism, syphilis, etc., and disappears as these diseases are cured. But they play no causal rôle nor do they possess any diagnostic significance. Familial cystinuria occurs especially in arthritic families. In as far as cystin in the body represents lowered rate of oxidation it should yield with other symptoms to remedies which promote oxidation. The ingestion of certain halogen benzols and salts of cystein is said to produce cystinuria.

Certain Important Sources of Error in the Phenolsulphonephthalein Test of the Renal Function.—Roth sums up as follows: The method is not suitable for pregnant women nor for women with affections of the genitals. The chemical must be used with great caution with especial heed that the injection fluid is not wasted. The solution should be absolutely trustworthy. In measuring off the urine care must be taken to recover all residual urine. If the amount voided seems too little it must be controlled with the catheter. Preparations from different manufactories differ much among themselves and yield different results. Injections should be made intramuscularly and by preference in the lumbal muscles; intragluteal injections give untrustworthy results.

August 26 and September 2, 1913.

Treatment of Lymphosarcoma.—Fabian sums up as follows: We may only venture upon surgical intervention in these cases when the seat of the growth is isolated and when we can exclude all similar lesions, such as might arise from leucemia, pseudoleucemia, malignant lymphonia, tuberculosis, and syphilis. We should perform radical extirpation whenever this is technically possible for there is upon record a series of successful operations of this sort without recurrence upon lymphosarcoma in the tonsils, pharynx, colon, spleen, and testicle. The least outlook for recovery is seen in what unfortunately is the most common type of the disease, to wit, lymphosarcoma, which takes its start in the external lymph nodes. Highly peculiar are the regressive changes seen at times in recurrent, inoperable, and generalized lymphosarcoma. These suggest attempts at recovery which, however, are only transient. Nevertheless, in such cases it is our duty to push all our therapeutic resources.

The Psychology of the Declarations of the Injured.—Foerster refers, of course, to injuries which call for financial compensation. The subject has undergone much discussion in the past few years. The testimony of the presumably normal witnesses differs much from that of the injured, undoubtedly as a result of the psychic shock which involves incidentally the memory, judgment, etc. The injured may find certain bruises upon himself which seem to bear no relation to the accident and tend to confuse him. Certain accidents in connection with the use of special apparatus (for example, the telephone) are often without witnesses. Certain operators hearing some peculiar sound which has, as they believe, injured the ear have reported most peculiar results, chiefly such as might be imputed to electric shock. These receive no

compensation because there is no external evidence of damage. They continue with their work for years, yet always maintaining that they should have received indemnity for symptoms which they attribute to the electric discharge. In general in many types of injury, the injured has a very defective notion of the amount and kind of damage because of the psychic insult, and some memories became extinguished, and afterward rehabilitated by conversation. In the aged and mentally diseased conditions may be much worse. The general public is unaware of this fallibility of the testimony of the injured.

Medical Observations in Central Brazil.—Aumann states that much misinformation exists in regard to sanitary conditions in this part of the world. He has just completed a sojourn in Rio, Santos, and Sao Paulo. In the first named city is the "Institut de Manguinhos" for the study of tropical diseases. There is also a museum of hygiene. All the cities have isolation hospitals, stations for emigrants, and for disinfection. Sao Paulo, by reason of its great altitude, is best suited for Europeans and regular sleep is possible. It has a serotherapeutic institute, and a vaccinogenic plant. Ordinary hospitals, in contrast with the preceding institutions, rather lag behind the times.

Treatment of Malignant Tumors.—Luckenbein first refers to his already reported attempts at treating inoperable cancer with its autolytic products. He notes benefit in both the primary and secondary growths. The interval has been too brief for the proofs of absolute recovery, but several authorities have reported quasi cures both of cancer and sarcoma. The substance used ought to possess great prophylactic virtues when used with other modern methods, especially the use of mesothorium. Roosing prepares his autolysate as follows: the extirpated growth, or even a portion excised from an inoperable growth or a gland metastasis, is finely comminuted in sterile physiological salt solution, shaken up thoroughly, allowed to stay on ice for three days, and then filtered. The filtrate is again sterilized by heating for one hour at 56° C. and is then ready for use. The author himself selects only closed non-infected tumors for autolysis, and carries sterilization to a greater extent, so that every receptacle and utensil is involved. The author also agitates the cancerous particles in the solution for one or two hours. Whether to concentrate or dilute the filtrate is a problem which the author has solved conditionally by making the specific gravity 1009-1010, which is the most suitable for injection. The intravenous method is preferred, and the extract must invariably be freshly prepared, and each extract employed for growths of its own origin. The theory of the success obtained is that the autolysate contains defensive ferments. It is advised to associate the treatment with sero- and vaccinotherapy.

Electrical Antifat Cures.—Schnée writes at length upon this subject. Its beginnings go back to the first introduction of the static machine. A systematic study based on experiment goes back only to 1897, when the author's father took up the subject. Naturally the subject of electric light baths is not included here as being a form of warm bath. The elder Schnée and his son the author tested the alternating and faradic currents, but also used all other known methods as synergists. The author made reports of his methods in 1910 and 1912. Several years ago Bergonié of Bordeaux introduced his now well known method in which electricity is for the time the sole resource used, and in which the value of the faradic current is well shown. After him came Nagelschmidt, replacing faradism with the Leduc current. In the meantime the author had been testing primary and secondary faradic currents, interrupted currents, the Leduc, semisoidal-faradic and other currents. All exerted some effect on muscular contraction, but this varied in its sensory component. The author has embodied his experience in a machine which he hopes to use in a great variety of conditions, although he names it "Schnée's Degrassator." He thinks "myomotor" might have been a more suitable designation because he hopes, like Bergonié, to treat muscular insufficiency of all kinds.

August 21, 1913.

Physiology and Pathology of the Thymus.—Meinhold considers especially the medullary hyperplasia of the organ, the status thymicus, and thymic death, and reports a personal case of the latter, due apparently to the application of the primary alternating current. Patient a vigorous male adult, who suffered only from some ear trouble. While undergoing tests for galvanic nystagmus, a weak faradic current was also employed, with interruption of one or two minute intervals. No ill results were noted, and he was referred to the psychiatrist for mental examination. Nothing abnormal was found and he was next referred to the neurological clinic, where he underwent a general faradization. He was somewhat excited and cried out, but submitted willingly. At the close of the seance he suddenly developed a tetanoid convulsion, which in two or three minutes caused death from cyanosis. A careful examination showed that the current was perfectly safe for the average patient, hence the need of invoking a predisposition. Autopsy developed nothing of this sort save persistent thymus. The medulla of the latter was the seat of marked hyperplasia. The patient's history showed a notable excitability, with tendency to phobias. He was fearful of military service, was prone to homesickness, and dreaded the electrization. In the thymic death there is a notable failure of heart and respiration. This species of death does not mean necessarily that death is due even indirectly to the state of the gland, or its mechanical compression of the trachea. Rather does a persistent thymus indicate a state of great bodily weakness or low vitality, as a result of which we see sudden death follow trifling accidents.

Juvenile, Traumatic Dissecting Epiphysitis of the Tibia.—Ebbinghaus states that in strong and healthy children at or near puberty a trauma affecting one or both knees may give rise to dissecting epiphysitis. The condition was first recognized by Schlatter about fifteen years ago. It is undoubtedly much more common than is believed, and school physicians should be on the watch for it. Diagnosis can be made only by *x*-rays, for Schlatter seems to have been ignorant of the precise nature of the trauma (he thought it might be either a separation or crushing of the crow's bill process of the tibial epiphysis). The condition is really an epiphysitis accompanied by detachment. The inflamed portion should be extirpated and the healthy detached portion restored. The operation may be done under local anesthesia.

Removal of the Dangers of Paraffin Embolism.—Hartney believes that in some quarters the fear of paraffin embolism is still present. He has worked out a method by animal experiment. We must make it impossible for minute portions of paraffin to enter the veins wherever regeneration of the latter is to occur. The remedy lies largely in the use of Esmarck's bandage to the extremities during and for some time after the injection, *i.e.* until all the injected mass has solidified. The filling of a bone cavity, etc., may thereby be practiced in safety. In case of forming a paraffin testicle, the same end is attained by the application of a slender rubber catheter about the penile and serotal veins. In certain other localities, as the breast, and especially the nose, various resources may have to be combined, and each case becomes a law to itself.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SELF SELECTION (*Continued*).

Self-Selection in Different Ages.—While adverse selection is constantly at work in all ages, it is exercised at times under peculiar circumstances among young and elderly applicants. Medical examiners will render material assistance to their respective companies by instituting a careful inquiry whenever one of these suspicious features is disclosed.

Self Selection Among the Young.—Medical selection in this country, more so perhaps than in Great Britain judging by a comparison of the mortality tables, has succeeded in eliminating a good proportion of the doubtful risks which formerly were accepted among entrants of from 15 to 25 years of age, and in reducing the death rates in this class in both countries to lower levels. Allowing for a mortality which has become lower on account of the improved conditions of living among the young and the preventive measures and modern treatment of infectious diseases, there still remains a tendency to a high death rate strong enough to invite the exercise of self selection, particularly in the cases of dependent non-supporting minors.

Statements explaining the object of the insurance applied for by these young people are usually to the effect that it will be taken with the idea of inculcating the habit of saving and creating a fund for use later in life. Such motives should be encouraged but a suspicion of speculation is immediately aroused when it appears that the individual who will pay the premium is at the same time the beneficiary. The payer of the premium in such instances is almost always the one upon whom the insured will have to depend for support, protection and care during illness. It has already been pointed out that these young people are tender, unseasoned, susceptible to disease and subject to a high mortality. They are, therefore, ready material for self selection, unconscious perhaps as far as they are concerned, but exercised for them by the payers of the premiums. Revolting as the idea may be, these facts must be considered, for history repeats itself in referring to the forgetfulness and cold neglect of some dependent when the person who should extend protection and support will gain financially by the death of the former.

Conscious self selection is more apt to appear in the advanced ages when the applicants have means to pay the premiums for themselves and have become more sophisticated.

Self Selection in Advanced Ages.—The selection of risks applying at from 60 to 70 is a difficult task. The special uncertain conditions encountered in this group probably account for the varying rates of mortality experienced by the companies ranging from only fairly satisfactory to excessive. These differences in experience must also be attributed in part to the standard of selection followed in each of the companies. A study of these lives clearly shows that the mortality is too high, on the whole, and, furthermore, that it has a tendency to increase, especially in the United States. This increase in the death rate may be ascribed primarily and principally to the strenuous business methods and the excessive indulgence in food, drink, and high living in general, which so often accompany the acquisition of wealth. It would almost seem from the data collected that the medical selection in this country has not always succeeded in keeping pace with these developing conditions and that it has been outstripped by a powerful self-selective force.

Men become more sophisticated, shrewd, and reticent as they advance in life and for these reasons cannot always be depended upon to be frank or to give out information freely, if at all, in regard to their feelings, symptoms, and ailments; furthermore, they become more conservative in parting with their money and not inclined to pay the large premiums which have to be charged to them for life insurance, unless they need the policy for very good reasons. The reasons may be quite legitimate, but, on the other hand, these applicants will often have some misgivings as to their hold on life and become anxious to make provision for their families at the expense of the other policyholders of the companies.

Other opportunities for self selection are presented in the cases of men and women between 55 and 70 who lend themselves to the designs of younger self-supporting relatives or relatives-in-law for the purpose of speculation when there are signs of advancing age or of some disease in the incipient stage. This self selection may be an unconscious one on the part of the applicants and exercised for them by those financially interested who will, also, usually pay the premiums.

Conclusions.—In selecting young risks there must be a close investigation into the personal and family history, the object for which the insurance is taken, the financial standing, and the character and surroundings of the applicant. The insurable interest of the beneficiary, especially if payer of the premiums, should always be definitely ascertained.

In regard to elderly applicants, the examination must be rigid and there must be a close inspection into the financial standing of the applicant and of his family relations and surroundings. The applicant must furnish sufficient evidence that he is able to and will pay the premiums. The investigation must be particularly careful whenever it appears that the beneficiary is a self-supporting child or son-in-law, and, furthermore, if it is established that such beneficiary will pay the premiums, the company will be fully justified in declining the risk.

Life Insurance and Medical Examinations.—At a meeting of the business committees of several Austrian and Hungarian Insurance Companies the following scale of fees was agreed upon: The examining physician is paid in proportion to the size of the policy. For one of any size up to 5,000 kr. his fee is 10 kr.; between 5,000 and 10,000 kr., 15 kr., while if the amount is 10,000 kr. or upwards he receives 20 kr. He must for this fee include the ordinary tests for albumin and sugar. The physician's attest must have each blank question fully and satisfactorily answered. If this is not the case the attest is returned to have vague answers and omissions cleared up. No extra fee is allowed for this service. The medical man is allowed mileage when he goes out of his district, and an extra 2 kr. for examining a man at his residence. The family physician is paid 8 kr. for his attest regarding a death.—*Zeitschrift für die ges. Versicherungs-Wissenschaft*, xiii, 1913.

Book Reviews.

HERBALS, THEIR ORIGIN AND EVOLUTION, a Chapter in the History of Botany, 1470-1670, by AGNES ARBER (Mrs. E. A. NEWELL ARBER), D.Sc., F.L.S., Fellow of Newnham College, Cambridge and of University College, London. Price $3.25. Cambridge: at the University Press; New York: G. P. Putnam's Sons, 1912.

THE main object of this book, the author tells us in the preface, is "to trace in outline the evolution of the *printed herbal* in Europe between the years 1470 and 1670, primarily from a botanical and secondarily from an artistic standpoint." Although the herbals are discussed from the medical side only incidentally, the book will yet be found of absorbing interest by any physician who has a taste for delving into the records of the past, especially if he has also some knowledge of botany. A list of the chapters will best give an idea of the scope of the book; these are: The Early History of Botany, The Earliest Printed Herbals, The Early History of Herbals in England, The Botanical Renaissance of the Sixteenth and Seventeenth Centuries, The Evolution of the Art of Plant Description, The Evolution of Plant Classification, The Evolution of the Art of Botanical Illustration, The Doctrine of Signatures and Astrological Botany, Conclusions. There are two bibliographical appendices, one a chronological list of the principal herbals and related botanical works published between 1470 and 1670, the other an alphabetical list of the principal critical and historical works dealing with the subjects discussed in this book. The illustrations, except portraits of which there are many, are copied from the various herbals. They are not all of plants for we note some very quaint drawings of a leopard, sparrows, peacocks, a unicorn playing in a lady's lap, an elephant, and other curiously fashioned beasts and birds.

THE BATTLE CREEK SANITARIUM. History, Organization, Methods. By J. H. KELLOGG, M.D., Superintendent, Battle Creek, Mich., 1913.

WHETHER one is a subscriber or not to the extreme views regarding diet, which are held and strictly practised at Battle Creek, it is interesting to learn at first hand just what the system is that is carried out in that institution, and the reasons therefor. This profusely illustrated book of 224 pages recites at length what is done there and explains why it is done. It is interesting to read and satisfies one's curiosity regarding a much talked of therapeutic method.

THE SURGERY OF THE STOMACH: A Handbook of Diagnosis and Treatment. By HERBERT J. PATERSON, M.A., M.C., M.B. (Cantab.), F.R.S.C., London. Price, $3.50. New York: William Wood & Co., 1913.

THE author describes in a concise and practical manner the diagnosis and treatment of those functions of the stomach which are amenable to direct surgical interference. He urges the test meal as one of the most essential diagnostic details in the investigation of gastric disease, and considers this procedure in its various aspects in the Appendix of the book. After taking up the methods of investigation of gastric cases and the preparation and treatment of patients before operations, he describes the technique of the latter, then considers the postoperative complications and the various stomach lesions of surgical importance. Mr. Paterson has had an extensive experience in operations of this character, especially with gastrojejunostomy, which he regards as one of the most important operations in the field of gastric surgery. He considers that the beneficial effects of the procedure in gastric ulcer are due to the entrance of the alkaline pancreatic juice and bile into the stomach. The acidity of the gastric contents is diminished about 30 per cent., and although gastric digestion is impaired after this operation, it is not entirely lost. Paterson does not regard this procedure as a drainage operation and the motility of the stomach for practical purposes is unaffected. Gastrojejunostomy moreover has no material effect on metabolism, the percentage of nitrogen and fat absorbed being within the limits observed in individuals who are apparently healthy. The book is illustrated with a great many half-tone plates made from specimens and dissections. Where these illustrations depict operative procedures they leave much to be desired as drawings of the modern type serve to render operative procedures much clearer than actual photographs of the same. Mr. Paterson's book is worthy of commendation as presenting in a succinct form our present day knowledge of the field of gastric surgery. It is only by repeated endeavors such as this, addressed to students and practitioners, that better results will be obtained, particularly in the malignant diseases of this organ in which as elsewhere, the risk of abdominal exploration is less than the risk of delay.

THE DIFFICULTIES AND EMERGENCIES OF OBSTETRIC PRACTICE. By COMYNS BERKELEY, M.A., M.D., B.C., CANTAB., F.R.C.P., LOND., M.R.C.S., ENG., Obstetric and Gynecological Surgeon to the Middlesex Hospital; Surgeon to In-Patients, Chelsea Hospital for Women; Senior Obstetric Surgeon, City of London Lying-in Hospital, etc.; and VICTOR BONNEY, M.S., M.D., B.Sc., LOND., F.R.C.S. ENG., M.R.C.P., LOND., Assistant Obstetric and Gynecological Surgeon to the Middlesex Hospital; Lecturer on Practical Obstetrics, Middlesex Hospital Medical School; Late Hunterian Professor, Royal College of Surgeons of England, etc. With 287 illustrations. Price $7.50. Philadelphia: P. Blakiston's Son & Co., 1911.

THERE are few branches of medicine in which on certain subjects there are such varying views and practices as in obstetrics. Methods that are condemned in one country are lauded in another, by men of equal eminence. It is therefore, of interest, in turning the pages of this book, to note some of the points in which the teachings of the authors, who stand in the vanguard of British obstetricians, differ from those current on this side of the Atlantic. They advocate the routine employment, in cases where a competent nurse is attending the woman, of vaginal douches after labor, basing this practice upon the fact that owing to the recumbent position of the patient, vaginal drainage is insufficient, and there is a tendency for the lochia to accumulate in the vagina and favor infection. For the same reason the authors are of the opinion that after all ordinary labors the patient should be allowed to sit up in bed on the day following labor, and to get up as soon as she wishes, provided that the temperature is normal. There is a great deal to commend this practice for it accords with the habits of primitive women and the hardier women of the lower classes. The treatment of occipito-posterior positions of the fetal head by means of manual rotation is the same as advocated by a group of prominent obstetricians in this country, with the exception that the authors delay this procedure until an advanced stage of labor rather than resorting to it as soon as the os is fairly well dilated. Exploration of the uterus is favored as a valid procedure in the early treatment of puerperal sepsis, and curettage is condemned. Cesarean section is given as the elective procedure in the treatment of contraction ring, as likewise advocated by certain obstetricians in this country. These are only a few examples of the fact that this work is based upon the authors' individual experience and not upon the teachings of others—a circumstance that immeasurably enhances the value of this book as a live one. There are many features about it that makes it one that should commend it to the general practitioner. The various obstetric procedures and operations are so clearly described with the aid of excellent and artistic illustrations of which there is a profusion, that the reader can have no difficulty in following the various steps. The authors do not discuss the physiology and management of normal labor, devoting their attention solely to the difficulties and complications. Many subjects that are omitted in the average textbook on obstetrics are here discussed in detail. For instance, childbearing in young primiparæ from eight to sixteen years of age forms an interesting topic. It is impossible to make adequate mention of many of the excellent features of this work, which is eminently practical, and certain to provide information in any difficulty that may arise in obstetric practice. In paper and typography, and above all in its artistic qualities this volume represents the best of the publisher's art.

DIE LIQUORVERÄNDERUNGEN IN DEN EINZELNEN STADIEN DER SYPHILIS. Ein Beitrag zur Biologie des Syphilisvirus im menschlichen Körper und eine Mahnung zur Vermeidung oberflächlicher Salvarsanbehandlung. Von Dr. WILHELM GENNERICH, Marine-Oberstabärzt. Mit 12 Tabellen. Price Mk. 2.80 Berlin: Verlag von August Hirschwald, 1913.

THIS brochure aims to throw light upon the syphilitic processes which lead to cerebral lues and metalues. The diagnosis of the liquor has attained special significance because clinical experience and experimentation have shown that it is very difficult to influence the spinal fluid therapeutically through the blood and therefore it is apt to remain the seat of a stubborn infection. The chapters deal with spinal fluid findings in primary syphilis, in the secondary stages, in recurrent secondary syphilis, in the tertiary stage, in latent syphilis, in meningocerebral syphilis, etc., etc.

Wayside Experiences. A Collection of Plain Tales as Heard Along the Road. By C. Elton Blanchard, M.D., Author of "The Letters of Dr. Betterman," "Medical Dollars and Sense," "The Nut Cracker and Other Human Ape Fables," etc., etc. Price $1.25. Newark, New Jersey: Physicians Drug News Company.

This is the latest addition to the newest kind of literature, namely that which aims at describing the effects of syphilis and gonorrhea, the so-called Social Diseases. The volume consists of a series of short stories, fairly readable, and occasionally interesting; fortunately there are no case histories of sexual diseases, and so the book is superior to some of the other volumes of a similar kind. In case a physician needs a book of this sort, the present volume may be of service.

The Psychoneuroses and Their Treatment by Psychotherapy. By Prof. J. Déjerine, Professor of the Clinic for Nervous Diseases of the Faculty of Medicine of the University of Paris, and Dr. E. Gauckler, Ancien Interne of the Hospitals of Paris. Authorized Translation by Smith Ely Jelliffe, M.D., Ph.D., Adjunct Professor of Diseases of the Mind and Nervous System, Post-Graduate Medical School and Hospital; Visiting Neurologist, City Hospital, New York. Price, $4.00. Philadelphia and London: J. B. Lippincott Company, 1913.

This book will especially please those who cannot bring themselves to believe that a Freud analysis only can cure the true psychoneurosis. There is no allusion to Freud anywhere in the text. Again those opposed to the so-called "rational" methods of Dubois, of Berne, in the treatment of the psychoneuroses, will also find Déjerine still a doughty opponent to a psychotherapy based solely on reasoning and argument. From Déjerine's point of view, "psychotherapy depends wholly and exclusively upon the beneficial influence of one person on another." The hysteric and the neurasthenic, the authors state, "are only cured when they come to believe in you" and have "confessed" their entire lives to you. "Sentiment and feeling" create an "atmosphere of confidence," without which, they say, no psychotherapy is possible. They are "convinced that in the moral sphere the idea alone does not move one, unless it is accompanied by an emotional appeal which makes it acceptable to consciousness and thus brings about conviction." They quote the ancient adage: "It is faith that saves . . . or cures."

Déjerine has spent many years in the practical study of the neuropath, and this book is entirely devoted to the development of a theory that the psychoneuroses are a very special nosological group, "whose symptomatology is caused solely by a primitive modification of the moral or mental state, followed by a whole series of secondary manifestations." The book is divided into three parts: the first comprises an analytical study of symptoms; the second, a synthetic explanation of the general mechanism of the foundation of the psychoneuroses, and their variations and nature; the third part contains all those psychotherapeutic proceedings and helps which, in the authors' opinion, should be used in treatment.

It will be noted by the reader that the authors deny any antecedent lesion of the body as a cause of the symptoms and troubles of the neuropath. They also hold that "neurasthenia is due wholly to psychological factors, and that these psychological factors are essentially, if not exclusively, determined by emotion." It is extremely interesting to read, and the authors ably uphold their point of view. Those functions of the body which are not completely automatic, but, on the contrary, depend in their ultimate accomplishment upon various mental manifestations and call the will into play, such as the digestive and genitourinary functions, are especially affected in neuropaths by the influence of emotions. This part is very fully dealt with. Also those functions, such as belong to respiration, on which the will acts only in a contingent way. Also, the purely automatic functions which may be affected by the influence of the emotions, though requiring no direction from the psychic centers

The understanding and treatment of the neuropath are exceedingly difficult. We are grateful to Dejerine and Gauckler for their excellent and suggestive work. Why should the fact that they lay special stress on the emotional side destroy entirely our appreciation of the value of Dubois's "appeal to the intelligence of the individual"? Why should their apparent reversal of cause and effect deliver some of us entirely from our convictions or wean us completely from our dawning interest in Freud? The reading of this book will help us in the treatment of many minor psychic disturbances which more or less incapacitate numerous individuals. Thanks are due to Dr. Jelliffe and his wife for an excellent translation.

The Triumph of American Medicine in the Construction of the Panama Canal. By J. Ewing Mears, M.D., LL.D. Third Edition, Revised and Enlarged. Twenty-one plates. Philadelphia: Wm. J. Dornan, 1913.

The fact that this book has passed through three editions in a comparatively short time is convincing evidence of its popularity. It presents in an interesting manner the mechanical and sanitary difficulties which were overcome in the construction of this great waterway. While the fact that great mechanical achievements involved in the undertaking were made possible by the even greater sanitary triumphs is well known and appreciated by the medical profession, the book should be welcomed as presenting these "marvels of courage, energy and scientific thoroughness, skill, research, and original discovery" in an attractive way and entirely within the comprehension of the average reader.

Zur Pathogenese, Klinik und Therapie der erworbenen Mastdarmstricturen. Von Dr. Ernst Ruge, dirig. Arzt am stadt. Krankenhause in Frankfurt-Oder. Price Mk. 1.50. Halle a. S.: Carl Marhold, 1913.

This small monograph is divided into two main parts, 1, the benign inflammatory strictures and, 2, the malignant strictures. In each case the etiology, symptomatology, diagnosis and therapy are discussed. The author's aim is to give a condensed birds-eye view of our present-day knowledge concerning the pathological and therapeutic influences that act on the strictures occurring in the rectum. The congenital stenoses and valvular formations are not discussed.

Die Ermüdung der Stimme. (Phonasthenie). Dr. R. Imhofer, Prag. Mit Zwei Notenbeilagen. Price Mk. 5. Würzburg: Verlag von Curt Kabitzsch, 1913.

A short historical sketch of this phase of laryngology is given, tracing the steps in the interesting development of the conception of phonasthenia. The nature of the clinical picture of phonasthenia is discussed. Statistics and etiology of phonasthenia are given. Diagnosis, prognosis, and therapy are expounded. An extensive bibliography is appended at the end.

Lehrbuch der Meeresheilkunde. Für Aerzte und Gebildete Laien. Von Dr. Arnold Hiller, Professor, Oberstabarzt a. D. Mit 1 Landkarte und 11 Abbildungen. Price Mk. 7. Berlin: Verlag von August Hirschwald, 1913.

The six main chapters of this work concern themselves with: 1. Sea air, including the action of light. 2. The sea bath. 3. Winter cures at the seashore. 4. Ocean voyages, sanatoria on ships and excursions for curative purposes. 5. Therapeutic retrospects. 6. Physical characteristics of sea baths. This last subdivision gives the practitioner at the seaside resort an insight into those diseases which have thus far been benefited by sea baths and gives the general practitioner living elsewhere the opportunity of choosing the time of year and the climatic conditions of those resorts that will most benefit his patient.

Der Magensaftfluss und verwandte Sekretionsstörungen. Von Sanitätsrat Dr. A. Günzburg, leitendem Arzt an der innern Abteilung des Krankenhauses der Israelitischen Gemeinde zu Frankfurt a. M. Mit 5 Kurven im Text und 4 Röntgenogrammen auf einer Tafel. Price Mk. 2. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1913.

This little monograph confines itself to the data necessary for understanding the secretory activity of the stomach and hyperchlorhydria. Short chapters are concisely devoted to the subjects of hypersecretion, gastrosuccorrhea, intermittent secretory activity of the stomach, hyperchlorhydria, and its relation to peptic ulcer, disturbances in the intestines in hyperchlorhydria, anatomical and experimental basic principles, diagnosis and therapy.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc., etc. Edited by Henry W. Cattell, A.M., M.D. Volume I, Twenty-third Series, 1913. Price $2.00. Philadelphia and London: J. B. Lippincott Company.

This number of this well-known quarterly contains nineteen articles on diagnosis, treatment, medicine, surgery, etc. Articles deserving special mention are those on Bence-Jones proteinuria by Boggs and Guthrie, retarded mental development in children by McCready, and Albee's method of bone grafting by Rugh. As a whole this volume seems to be rather less satisfactory than this publication usually is. The résumé for 1912 is very comprehensive.

Society Reports.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held March 4, 1913.

THE PRESIDENT, DR. SMITH ELY JELLIFFE, IN THE CHAIR.

A Case of Acute Infective Encephalitis, Probably of Gonococcic Origin.—Dr. JOHN H. LARKIN and Dr. SMITH ELY JELLIFFE reported this case and showed the specimen. The patient was a Hungarian, 33 years of age, who had apparently enjoyed perfect health up to the time of his present illness. He was admitted to the City Hospital on the 13th of January, 1913, suffering from a urethral discharge. After spending a day or two in the genitourinary ward it was observed that he was not quite clear in his mind and he was transferred to the neurological service. At this time he complained of pain in the legs and bladder, and he had so much difficulty in passing his urine that he had to be catheterized. There was a slight discharge from the penis and constant priapism. Because of his mental condition it was impossible to elicit a satisfactory family history. With the exception of a slight increase in the reflexes of the lower limbs some spasticity and a doubtful Babinski, the neurological examination proved negative. There was no temperature elevation at this time. Shortly afterward the eyes were examined by Dr. Louis Casamajor, who reported beginning choked disk. Graually, the spasticity of the lower limbs increased, his mental condition became worse, he became more apathetic and less and less responsive, the choked disk became more apparent, especially on the right side, and these symptoms, together with the prominence of the spastic phenomena on the left side, led to the determination to make an exploratory opening over the right frontal lobe, in the hope of finding a tumor or other lesion to explain his symptoms. The patient's temperature, which had been normal at the time of his admission, gradually rose to 101°, then fell to normal, and again rose to 100°, where it remained until the day of his death, when it fell to subnormal. Upon exposing the brain, nothing abnormal was found on gross examination. The patient died, and the autopsy was made by Dr. Larkin, who made the following preliminary report: The brain, which weighed 1400 grams, was somewhat flattened on the left side, and was the seat of an acute form of encephalitis, in which the preponderance of the cells were of a large, irregular type, invading the white matter, with marked infiltration of the walls of the blood vessels. The gray matter was not involved. This patient, at the time of his death, had a gonorrheal infection of the posterior urethra, and smears, taken from the brain, showed a peculiar organism, a Gram positive bacillus, which by culture on serum agar gave a light growth corresponding very closely to that obtained from gonococci. On retransplantation, however, the cultures died out, and Dr. Larkin said he was therefore unable to positively assert that the encephalitis was of gonococcic origin, although that was his belief.

Tumor of the Spinal Cord.—Dr. WILLIAM M. LESZYNSKY presented the spinal cord removed from a woman 49 years of age. For nine years she had complained of characteristic root pains in the course of the left sciatic and anterior crural nerves, and at the end of the fourth year the right lower extremity became similarly affected. Subsequently there were paresthesiæ, attacks of transient loss of power in the extremities, and a band-like feeling at the level of the lower thoracic region. Ultimately she became completely paraplegic, with bilateral footdrop, loss of patellar, Achilles and plantar reflexes, and incontinence of urine. Hypalgesia and thermoanesthesia extended upward to several inches above the level of the umbilicus. The tactile sensibility was preserved. The Wassermann reaction was negative. Although several lumbar punctures were made no cerebrospinal fluid could be obtained. The diagnosis was made of a tumor involving the cauda equina, with secondary implication of the cord. At the operation, which was done by Dr. Charles A. Elsberg, a large tumor was exposed which filled the entire lower part of the spinal canal and extended to and over the conus. Most of the growth was removed within its capsule. No improvement followed, and death took place from exhaustion three months later. At the autopsy a tumor mass was found involving the cauda and filling the sacral canal. This was a glioma. There were syringomyelic cavities in the lumbar and thoracic regions, chiefly in the anterior portions of the posterior columns, with borders of pronounced gliosis. Both the ascending and descending tracts showed advanced degeneration.

A Demonstration of the Syphilitic Organism in the Brain in Paresis.—Dr. J. W. MOORE read a paper on this subject and exhibited a number of microphotographs showing the presence of the *Treponema pallidum* in the brain tissues of a paretic. The inception of this work, the writer said, and the preparation and staining of the specimens were his own, but the credit of having been the first to see the organism belonged to Noguchi of the Rockefeller Institute, to whom he loaned a duplicate set of slides for the purpose of looking for a possible granular form of the spirochete. The findings were published in the *Journal of Experimental Medicine* for February 1, 1913. Dr. Moore said that from his autopsy service at the Central Islip State Hospital he had a fairly large number of paretic brains in his possession. Early in 1912 a systematic search of these brains in groups of twenty and thirty was made for the *Treponema pallidum*. Seventy brains were thus examined, the cases being clinically and anatomically satisfactory as to the diagnosis of paresis. Without entering into the details of the technique of staining, the speaker said the Levaditi silver method was used, with some modifications which might or might not have been important. An unusually favorable degree of staining resulted in many of the specimens. Noguchi was the first to see the organisms, and found them in variable numbers in twelve out of the seventy cases. Immediately after learning of Noguchi's finding the speaker said he was able to locate the spirochetes independently and without much difficulty in all of these twelve cases. In about one-half of these cases they were very scarce, but in several they were quite numerous and not at all hard to find. The reason why the writer himself had not seen them during prolonged searching was due to a most interesting and significant fact regarding their location. Having in mind the chronic inflammatory changes which one found in paresis, namely, the infiltration of the pia and vessel sheaths with lymphoid and plasma cells, the writer devoted his attention almost entirely to these localities, particularly as it was here that the organisms had been found in cases of cerebral syphilis, in the narrower sense. In paresis, however, they were apparently absent in the pia and were seldom seen in the immediate neighborhood of the visible vessels. They occurred, instead, deep within the tissue of the cortex. Their motility and penetrating power was known from dark-field observation and from Noguchi's cultural experiments, and it was evidently by this means that they had found their way to the locations where they were encountered. They were almost always in the nerve-cell layers of the cortex; seldom in the marrow, and never in the external neuroglia layer, so far as the observations in these few cases went. Dr. Moore said it was apparent at once how important the knowledge of the existence of the syphilitic organism in paresis was, but he wished to call attention to a few of the more salient points. First, we were afforded a tangible cause for the chronic inflammatory reaction if not for the degenerative changes in paresis, and one which corresponded fairly satisfactorily in location and distribution. It was no longer necessary to offer theories of metabolic disorder, overproduction of anti-body, deficiency in lecithin, etc. In the actual presence of the treponema we saw the reason for the serological findings in blood and spinal fluid. The difference between paresis and cerebral syphilis could be conceived to be only one of location and distribution of the organism. When we considered the results of the experiments with vital staining, which showed that fluids introduced into the circulation practically never reached the depths of the brain tissue, or at most only the superficial neuroglia layer, and also that potassium iodide and even antigens and immune bodies did not pass through the meninges, the inefficiency of anti-syphilitic treatment in paresis, whether it be introduced into the circulation or spinal canal, was made clear. The outlook for the future was also rather hopeless, since the organisms lay at a depth at which they apparently could not be reached by ordinary methods.

Dr. CHARLES B. DUNLAP said there was very little to add to the presentation of facts that Dr. Moore had given. After various modifications of the Levaditi silver method Dr. Moore obtained a very clear stain, showing the spirochetes (*Treponemata pallida*) jet black against a yellow background. The fact that Dr. Moore failed to find the organism in his earlier examinations was not surprising; they were found not in the mesoblastic tissues, where he had been especially looking for them, but free in the cortical tissues, and one might search through many sections from various parts of the brain and find none. The

results of this work by Drs. Moore and Noguchi, the speaker said, were far reaching, since they proved (if confirmed—and there was scarcely a doubt that they would be confirmed) what had long been suspected, that the *Treponema pallidum* was the essential causative factor of general paralysis, but this clearing up of the etiology in no way lessened the clinical or anatomical value of the work previously done in connection with this subject. General paralysis would still stand as a distinct variety of cerebral disease, distinct in its anatomical features from other forms, distinct as a clinical group, and distinct in its failure to adequately respond to therapeutic agents and methods heretofore effective in the treatment of ordinary syphilis. While this was so, the demonstration of the treponemata rendered the problem of future therapeutic attack much more definite and more hopeful.

A Case for Diagnosis.—Dr. William Steinach presented a man, 69 years old, a native of Germany and a machinist by occupation. He stated that his father, who died at the age of 78, of cardiac disease, had some sort of a tremor. His mother died in childbirth. The patient was the father of eleven children, of whom seven were living, four having died in infancy. One son was a deaf mute, the result of some meningeal trouble following an injury to the head in childhood. Aside from this there was no history of any nervous or mental disease in the family. The patient denied lues and had always been temperate in his habits. He had malaria and typhoid fever in childhood. He was well and worked regularly as a machinist in a safe manufactory up to November, 1892. At that time, while bending over, he was struck on the back of the neck by the end of a bar of steel, two inches thick and fourteen feet long, weighing fully 120 pounds. He was knocked unconscious and remained so for fifteen minutes. He was taken to his home and shortly afterward began to complain of headache, pain in the back of the neck, fatigue on slight exertion, and inability to work. About two months later he became depressed and developed suicidal tendencies, when he was sent to Ward's Island, where he remained for six months. About a year after his injury the patient developed a tremor which became much aggravated on intentional movements. About eleven years ago he developed convulsive attacks which had recurred more or less regularly about three times weekly. He also had daily attacks of transient dizziness. His convulsive attacks were at times accompanied by total loss of consciousness; at other times the loss was only partial. Sometimes he cried out, foamed at the mouth, and bit his tongue, and after the more severe attacks he generally fell asleep. There was no aura. During his attacks, as repeatedly observed by Dr. Steinach and others, he alternately stiffened and relaxed. The seizures had rather the character of hysteroid attacks. His memory afterwards was very hazy. Aside from the intention tremor, the patient showed no organic symptoms. His pupillary and knee reflexes were normal; his abdominal and cremasteric reflexes were present. He had no Romberg. His eye grounds, as reported by Dr. S. M. Ingerman, showed a slight pallor on the temporal edge of both disks. In connection with this case, Dr. Steinach offered the following conclusions: 1. The persistence and severity of the symptoms after the lapse of over twenty years. The man was wholly incapacitated from performing his usual duties. 2. The absence of litigation or any question of damages, which was a strong feature of most of the traumatic neuroses. 3. The strong resemblance of the condition to multiple sclerosis. 4. While a tentative diagnosis of traumatic neurosis had been made, there was a question whether some organic changes had not been superadded.

Dr. J. Ramsay Hunt, who had seen this patient some years ago, said he could never find any definite signs of organic disease. While he regarded it as a case of traumatic neurosis or psychosis, it had always seemed to him, from the severity of the injury, that there might have been some organic lesion.

Dr. Leszynsky, who had had this patient under his observation about fourteen years ago, said he had noticed that his symptoms always seemed to become more aggravated when he was being exhibited.

Dr. L. Pierce Clark thought that in spite of the fact that the tremor became more intense when the patient was under observation, the condition had existed so long that we probably had to deal here with some organic change rather than a purely traumatic neurosis.

Dr. Benjamin Rosenbluth said that in a similar case seen at the City Home six or eight years ago, where the tremor came on after an injury and was diagnosed by successive visiting physicians as a traumatic neurosis, the post mortem disclosed a lesion in the thalamus.

Spinal Decompression for Meningomyelitis.—By Dr. Alfred S. Taylor and Dr. J. W. Stephenson. The patient was a married man, 62 years old, a watchman on the railroad, whose previous history was negative with the exception of an attack of pleurisy and pneumonia seven years ago. His family history was unimportant; there was no history of lues; no cough. The patient's present illness began in May, 1912, when while at work he was seized with an intense pain in the chest and back, which became very sensitive to the touch. He was taken home, and for several days the pains persisted. He was delirious and was said to have fever. His condition was diagnosed as rheumatism and so treated. Two weeks after the onset of his illness an abscess developed on the right chest; this was incised and its contents evacuated. At this time he also suffered from retention of urine and his testicles became swollen. This, however, soon cleared up. The pain and fever persisted intermittently, recurring at variable intervals, and early in August, the pain "seemed," according to the patient's statement, to locate in the neck and back of the head and was followed by a heaviness of the legs and consequent difficulty in walking. The legs gradually became stiff, and in place of the pains he began to have "cramps" which would double him up. In the course of time he also noticed that the upper extremities were growing weak and stiff, and all symptoms gradually progressed until about the middle of August, 1912, when the patient became bedridden. He also complained of considerable pain over the region of the bladder, and examination revealed retention, with overflow. There was obstinate constipation. When the patient was admitted to the Neurological Institute, on November 13, 1912, in the service of Dr. Frederick Peterson, he was unable to walk or stand, having been bedridden for three months, and complained of paroxysmal cramps in the legs. Examination revealed a marked spastic paraplegia, with decided weakness of both upper extremities. He was unable to feed himself, and voluntary movements of lower extremities were impossible. The bladder was distended and there was impaction of the colon. There were no distinct atrophies, though the leg muscles were flabby. There was no tenderness over the vertebræ, but on the right side of the neck, over the lower three cervical vertebræ, there was a distinct infiltration which was tender on pressure and which somewhat limited the movements of the neck. Over the right chest, just underneath the clavicle, there was slight infiltration which was attributed to the old abscess. The knee jerks were plus plus and equal; the ankle jerks were plus and equal; there was a double Babinski and Oppenheim. There was double ankle clonus; the right inexhaustible, the left exhaustible. The abdominal and epigastric reflexes were very sluggish; those of the upper extremities were plus, L > R. There was a diminution of the thermal, pain, and tactile sensations up to the level of the first dorsal. The eyes were negative excepting for a slight irregularity of the pupils. The patient's temperature was 98°; pulse, 68; respirations, 18; blood pressure, 140 mm. A blood examination showed 4,778,000 red blood cells, with 9,600 leucocytes. A differential count showed neutrophiles, 62; large lymphocytes, 15; small lymphocytes, 22; transitionals, 1. The morphology was negative, as were also two serum Wassermann tests. Uranalysis was negative; the von Pirquet test was negative. The patient was kept under observation for twenty-eight days, during which time there was a gradual progression of symptoms: areas which previously showed a sensory diminution became anesthetic, the abdominal and epigastric reflexes disappeared, and the left exhaustible clonus became inexhaustible. The cramp-like pains became more severe and frequent, requiring the use of morphia. Frequent catheterizations became necessary, and the bowels were evacuated only by means of enemata. An *x*-ray was taken by Dr. Cole, which showed a circumscribed shadow on the right side of the spinal column, opposite the sixth cervical vertebra, which was apparently just in front of the transverse process. The case was referred to Dr. Alfred S. Taylor, who did a hemilaminectomy on December 10. Four days after the operation, an examination revealed an exhaustible clonus, and pin pricks were felt acutely by the patient over the previously anesthetic areas. On December 18, the patient was able to move his legs voluntarily, and from this time on his condition gradually improved. On December 26, with some assistance, he was able to walk the length of the ward, and the bladder and rectal functions were restored. He had an occasional "cramp," but never required opiates.

Dr. Alfred S. Taylor, who performed the operation in this case, said there were one or two points in connection with it that perhaps should be brought out with a little more emphasis. Early in the course of this man's illness

he developed what was regarded as an abscess at the junction of the sternum and the second costal cartilage. This was opened, but after two or three months it still contained some old, chronic inflammatory material; it appeared as a distinct swelling, slightly tender, and was very suspicious of a gumma. Of course, the fact that the Wassermann reaction was negative rather militated against that theory, and the abscess was possibly of tubercular origin. The von Pirquet test, however, was also negative. Another suggestive point was the evidence of the presence of inflammatory material on both sides of the spine over the actual seat of the trouble. The transverse processes of the fifth, sixth, and seventh cervical vertebræ were more or less indistinct in outline on account of the presence of this material. Dr. Taylor said the operation he had done in this case was an exploratory right hemilaminectomy. There was nothing unusual observed in the laminæ themselves. When, however, the laminæ were removed and one came down on the dura, the latter seemed to fill the entire spinal canal. The cord itself was somewhat congested, so that it entirely filled the dural cavity, interfering with the flow of spinal fluid. The cervical canal, instead of widening as it ordinarily did, was distinctly narrowed. Apparently, there must have been a combination of a congential malformation, plus some inflammatory condition of the cord. In completing the operation, the dura was not sutured. The bone was not replaced and the muscles were sutured.

Dr. Hunt said that syphilis of the vertebral column was rare, but should always be considered in cases of spondylitis. The cervical region was most frequently involved in this group of cases, and the meninges or the cord might be compressed or directly involved by the syphilitic process at the same level. In the case reported by Drs. Taylor and Stephenson, a syphilitic periosteitis and osteitis with consecutive peripachymeningitis should be considered as a possible clinical diagnosis.

Dr. Clark said he did not think we were entirely justified in ascribing the condition in this case to syphilis, as that diagnosis was not borne out by the serological tests. While these spinal decompression operations often proved apparently beneficial, the speaker said he was inclined to believe these cases should be investigated a little closer and sifted out a little finer before an operation of this kind was recommended. Although a decompression operation was beneficial in a certain few cases, it was still a rather questionable procedure in cases where the diagnosis was obscure.

Dr. Larkin said that from the presentation of the case, as made by Drs. Taylor and Stephenson, he did not think a diagnosis was at all possible. A syphilitic osteitis or periosteitis, such as had been suggested, could easily have been demonstrated from its objective features. A specific inflammation of the meninges of the dura spinalis would certainly have showed some objective features to give rise to such phenomena as this man had presented.

Dr. Foster Kennedy said he did not agree with Dr. Larkin that a syphilitic pachymeningitis always presented such clear objective features that it could not well be mistaken for anything else. When one had cut down on the cord and found an inflammation of the dura mater, it was not always easy to say whether it was tuberculous or of specific origin. Replying to Dr. Clark, the speaker said he saw no objection to advising an exploratory operation in a case of this kind. The man had certain definite symptoms pointing to a certain area of the cord: he was obviously growing worse, and even if the operation had failed to produce any improvement in his condition it would still have been warranted.

Dr. S. P. Goodhart said he did not think conditions similar to this were so very uncommon, and he recalled a case in his practice, operated on by Dr. Taylor about two years ago, in which the condition was practically the same. The operation, as in this instance, consisted of a decompression. That patient was seen by Dr. Dana, who concurred in the diagnosis of suspected neoplasm. A decompression was done, both for relief of pressure and for exploration, and although no tumor was found, the patient improved very much. There was no other way in which she could possibly have obtained that relief. The cord at the site of operation showed congestion. The motor and sensory symptoms before operation pointed positively to a localized lesion at approximately the second dorsal segment. Decompression and exploration in these cases was justified and even imperative.

Dr. J. F. Terriberry said he understood that antisyphilitic treatment was not given a trial in this case, as it was taken for granted that the condition was not specific, based on the pathologist's report. Was that a safe and sound doctrine? Was it right to proceed surgically in a case of this kind before giving the patient the benefit of a thorough course of antisyphilitic treatment? The speaker said he recently saw a case with a condition of the ribs very similar to that described in this instance, and the lesion cleared up entirely under specific treatment.

Dr. Taylor, in closing, said he had not made the statement that the spinal lesion was specific; only, that the so-called abscess on the rib looked like an old gumma, but that the laboratory tests had barred out syphilis. The test of the serum and spinal fluid both gave negative results. Replying to Dr. Terriberry, he thought we were not justified in losing time by subjecting a patient in such a condition and one who showed no evidence of syphilis to a course of antisyphilitic treatment when that time could be used to better advantage. The bones of the spine did not show any evidence of disease; as far as could be made out, they were normal in appearance. Nothing abnormal was observed until he reached the dura, which might have been slightly thickened, but this was doubtful. The leptomeninges seemed thickened and congested, as was the entire exposed cord. The entire spinal canal was occupied by the congested cord, leaving no room for spinal fluid, and it seemed reasonable to suppose that we had to deal here with an old chronic inflammatory process, with resulting symptoms due to compression of the cord.

The Traumatic Neuroses; A Retrospect and a Forecast.—Dr. Pearce Bailey presented a paper on this subject, in which he said that considered retrospectively the traumatic neuroses fell naturally into three periods: First, the initial, organic period of Erichsen; second, the functional period, made possible by the work of Charcot; and, third, the modern, analytical period, which had encouraged the psychological dismemberment of hysteria. While these disorders existed before Erichsen's time, their history dated from the appearance of his book, which came stamped with the great authority of England's foremost surgeon. It had an enormous sale, ran through many editions, and its influence even to-day was not entirely eradicated. By publishing the amounts of money paid plaintiffs by corporations which had injured them it showed how important a railway injury might prove as a personal asset and brought to the attention of medical men and lawyers alike the devastating effects which railway and allied accidents might exert on the human nervous system. Under the heading of "spinal concussion," a term no one knew the exact meaning of, Erichsen brought together a great number of clinical conditions which had no relation to one another excepting in so far as any of them might appear in the victims of railway or other casualties.

As knowledge of the anatomy and physiology of the nervous system and the symptoms of its diseases progressed, some of the errors of Erichsen's work became apparent. It became evident that a fracture of the spine was the same whatever the accident that caused it, and that locomotor ataxia, developing in direct sequence to a railway collision, did not disprove that the man who developed it had syphilis, or that he would not have become ataxic without any accident. But while these frankly organic cases found their true place with advancing knowledge, it took much longer for the purely functional nature of imposing physical symptoms to be recognized, and when this happened, in Charcot's great days at the Salpêtrière, the traumatic neuroses entered upon the second or functional period of their history. For many years, during this period, the traumatic neuroses consisted of traumatic hysteria, such as Charcot described, and of traumatic neurasthenia. There were other neuroses advanced from time to time as characteristic of accidents, but these two were the chief and most important ones. A true traumatic neurosis, in which the question of fraudulent simulation can be excluded, may be regarded as a more or less subconscious expression on the part of the plaintiff of his wishes or of his fears, his mind having been thrown back to a more primitive state by the accident. With the high money premium put on personal injuries, it was easy to see in what way these wishes might point, but the desire for financial profit, while it was doubtless important, had, in the reader's opinion, been very much overestimated in the original genesis of this affection. It seemed to him in a very long experience that a desire for revenge against the person who had injured him was a very much more potent force in determining the changes in personality. He had yet to see a plaintiff who was not extremely bitter against the offending party.

Dr. Bailey said the study of the traumatic neuroses had always been hindered by the fact that it rarely was possible to get at all the conditions of the case, and they had rarely been studied from the analytical point of view

which had thrown so much light upon neuroses of other origins. If the hypothesis which he had set forth was correct, the explanation of every traumatic neurosis must be found in disturbances of consciousness: the accident affected consciousness more or less violently, and at once began to loosen restraint in the subconscious regions. The individual symptoms of traumatic neuroses, namely, the hemiplegia, the paraplegia, the blindness, etc., which had been regarded hitherto as the most important, seemed to him important only in so far as they gave a clue to mental motives; they were the clinical expression of fear or desire; their particular form was determined partly by the general makeup of the patient and partly by environmental conditions. Outlook: Statistical inquiries undertaken for the purpose of deciding what proportion of cases of traumatic neuroses recovered had always been extremely baffling. It had rarely been possible to secure accurate information of a sufficiently large number of injured persons for two years after the accident to make the results adequate. The writer's own experience with cases originated as traumatic hysteria had been that before the legal case was terminated, there was little or no improvement; that after the case, as such, was terminated, there was eventually disappearance of the physical symptoms, such as paralysis, etc., in almost every case. This recovery did not occur immediately, as claim agents maintained, and might be delayed several months or years.

Dr. Clark, after complimenting Dr. Bailey upon his excellent presentation of this subject, said he agreed with the writer's view in regard to the outlook in these cases of traumatic neuroses, and thought it was unfortunate that some psychoanalyses had not been made in order to learn the actual outcome of these cases after so-called recovery had taken place. Even an ordinary analysis of a large material after litigation had not been undertaken.

Dr. Steinach said he thought Dr. Bailey had taken a rather one-sided view of the subject. In the case he had shown tonight, for example, the injury had occurred over twenty years ago and there had been no thought of litigation. Some of these patients, at least, were not actuated by feelings of revenge or financial profit.

Dr. Maloney said the personal experience related by Dr. Bailey was very interesting, especially the fact that the sense of fear developed afterward. Quite a lot of data bearing on this very point had been collected through the Society for Psychical Research.

Dr. Goodhart said that Dr. Bailey, in regarding revenge as a potent factor in determining the changes in personality in many of these cases, really overlooked the essential point in the psychopathology of the situation, as he had endeavored to correlate it in his scheme. Revenge, as asserted in those cases, was purely a voluntary conscious reaction: the real activity of the subliminal consciousness expressed itself later in the development of a true fear neurosis, out of which the various forms of phobia might develop.

Mescaline and the Psychology of Optic Hallucinations.—Dr. W. J. M. A. Maloney and Dr. A. Knauer presented a paper on this subject, which was briefly discussed by Drs. Kennedy, Rosenbluth, and Onuf.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held April 24, 1913.

Dr. George Gray Ward, Jr., in the Chair.

Echinococcus Cyst of the Liver.—Dr. Hermann Grad reported this case. He stated that this condition was rare in America and that it was interesting to note the manner in which this tapeworm reached the human being. The disease was caused by the larvæ of a tiny cestode, the *Tænia echinococcus*, which infected the dog. The fertilized eggs were passed along with the excreta or the segments were covered with some mucus by which they adhered to the grass or other substances which herbivora ate. Thus the ova reached the alimentary canal of the host. Each ovum consisted of an embryo enclosed in a fibrous capsule, which latter was digested by the gastric juice, thus setting the embryo at liberty. This embryo was capable of boring its way into the walls of the stomach and of causing serious local injury to the tissues which it pierced, and it might thus reach the systemic circulation and be carried to any part of the body. As a rule they were stopped by the liver, having reached that organ by the portal circulation. The embryo having reached a stationary position in some solid organ began to develop into the characteristic bladder cysts, the so-called hydatid. These cysts might be found growing in the liver, respiratory organs, peritoneum, circulatory apparatus, brain, spinal cord, spleen, kidneys, and suprarenals, in the substance of muscles, subcutaneous tissues, medullary cavities of bone, in the orbit of the eye, in the breast, axilla, scrotum, ovaries or uterus. In Iceland, where the disease was very prevalent, the echinococcus growth was found in the liver in 69 per cent. of the cases. The lung was affected in about 1 per cent. of the cases and the peritoneum came next. These hydatids were also found in many animals. After describing the development of the embryo into bladder cysts, daughter cysts and brood capsules the writer called attention to the fact that these cysts might vary greatly in size and rapidity of growth, some even remaining stationary for years and yet retaining their vitality. As a rule the greatest growth was observed where the greatest space was afforded. When they grew from the under surface of the liver they attained a great size, as the intestines were easily displaced. A hydatid cyst might be found dead in any stage of development, or the contents might be found degenerated into a solid caseous mass, showing a morphous débris and hooklets under the microscope. Again a hydatid cyst might be converted into a circumscribed abscess. The process of degeneration rendered these parasites inert. An urticaria eruption often followed the tapping of an echinococcus cyst, more especially when the cyst was situated in the abdominal cavity. These rashes had been known to occur independently of operative interference and to be ushered in with an attack of giddiness and vomiting. Alarming symptoms had been observed to follow the tapping of the cyst, when there was reason to believe that the fluid had gained entrance into the blood stream. Cases of a fatal issue following a simple puncture of the cyst had nearly always been confined to punctures of the abdominal cavity, except in one case in which the tapping of a pulmonary hydatid caused death from flooding of the bronchi.

The case that Dr. Grad reported occurred in a young woman, 24 years of age, who had been married for one year and had one child. She had been ill for about three years and complained of pain in the upper abdomen, attacks of indigestion, a general feeling of illness and jaundice which had lasted for two years. A diagnosis of cholelithiasis had been made on a previous occasion and had been confirmed, according to the statement of the patient, by the *x*-rays, which showed the shadows of the stone. A careful physical examination again led to a diagnosis of cholelithiasis and operation was advised. Upon opening the peritoneal cavity they were surprised to find a tumorous mass situated under the dome of the diaphragm, which was adherent to the left kidney, the spleen, and the spinal column. Further examination showed the gallbladder to be normal and that the large masses were intimately connected with the left lobe of the liver. The adhesions were friable and easily severed. It was decided to enucleate the mass, although the diagnosis was not clear at this time. The trocar brought forth a small quantity of clear fluid, and in withdrawing the cannula a small echinococcus bladder protruded through the aperture, which gave a clue to the diagnosis. They proceeded to enucleate the mass, but in severing the growth from the liver structures a sudden and alarming hemorrhage set in which could only be controlled by suture of the liver tissue. The peritoneal tissue was unavoidably soiled with the cystic fluid. Hundreds of echinococcus bladders were evacuated. The patient stood the operation poorly and required an immediate intravenous injection of saline solution. A tank of oxygen was used, the gas bubbling through a 50 per cent. alcohol solution instead of through clear water. It was of great interest to see how this succeeded. It was used for three days and the patient finally made a complete recovery. The report of the pathologist showed that the tumor was an echinococcus cyst of the liver, irregular in size, with a ragged surface and was hemorrhagic. It held almost a quart of fluid. The wall was composed of dense hyaline membrane of several lamellæ. Several daughter cysts containing gelatinous white bladders like opaque daughter cysts with elastic walls were present. Microscopically the contents showed the characteristic scolices with rosettes of hooklets, cholesterine crystals, and droplets. The microscopical examination of a section showed the lobules of hepatic tissue surrounded with dilated bile ducts, the whole being infiltrated with pus cells and hemorrhage.

A Case of Multiple Neoplasm.—Dr. Porter Flewellen Chambers made this report which was read by Dr. Grad. The patient, a woman 42 years of age, was admitted to the Woman's Hospital on January 18, 1909. She had been married twenty years, had no children, but an indefinite history of a miscarriage. During the few

months previous to her admission to the hospital she had noticed that her left breast was sensitive and that a small mass was palpable, but there was no enlargement of the glands, no retraction of the nipple, and no shooting pains. On January 19, 1909, this mass was removed as well as the surrounding healthy breast tissue. From the frozen section the pathologist reported a condition of chronic mastitis. During the summer the patient again noticed a sensitiveness of the breast that had been operated upon and the pathologist disclosed the fact that a more careful examination of the specimen had pointed to a suspicion of malignancy. On November 30, 1909, a Halstead operation was performed on the left breast. On December 10 the patient developed a severe pain in the left side of the abdomen which lasted for four days. An examination disclosed a fibroid of the uterus and adnexal disease. The breast contained a few hard nodules which were scattered throughout the gland, but the muscles were apparently not involved. The axillary nodes were slightly enlarged and hardened. Carcinoma of the axillary glands was diagnosed. The patient was admitted to the hospital three weeks later, complaining of pain along the left border of the tongue and a puffiness of the supraclavicular region. She was referred to Roosevelt Hospital in order to receive Hodenpyle's injection intravenously, which greatly aggravated her nervous condition. She was readmitted to the hospital for the fourth time on July 25, 1910. On the following day an operation was done for the uterine fibroid; a urethral caruncle was removed, and also a salpingo-oophrectomy and an appendectomy were done. The pathologist's report on the uterine condition showed mural and subserous fibroids. A diagnosis of fibroid myomata, one fibroid degenerating, and chronic appendicitis, was made. A year and a half after this operation the patient was again operated upon for a tumorous mass in the right breast; the breast was removed and all suspicious masses enucleated. The pathologist's report on this specimen showed a mixed cell sarcoma, intraclavicular node, and scirrhous carcinoma of the breast. The patient was discharged from the hospital on December 23, 1912, and readmitted January 15, 1913. She had a tumorous mass of the top of her left shoulder and a similar mass in the abdominal wall; both masses were removed under local anesthesia. The pathologist reported that the specimen was a mass of dense, mostly parallel spindle-shaped elements, replacing the primary tissue completely. There were several lumina of blood vessels in the tissue, but no certain relationship with them could be ascertained. A diagnosis of spindle-celled sarcoma of metastatic origin was made. Her attending physician reported that general sarcomatosis of the skin supervened and she died on February 22, 1913.

Profuse Intraabdominal Hemorrhage without Evident Explanation.—Dr. LeRoy Broun reported this case. The patient, a woman, 45 years of age, had menstruated with a fair degree of regularity, the length of time being from five to six days. When a child she had had profound anemia and had flowed for only a day at a time and then suffered occasionally with great pain. The anemia persisted for fully fifteen years, during which time she could not go upstairs without suffering from cardiac attacks. When the patient was first seen in January 3, 1913, she was in a state of extreme collapse with every evidence of internal hemorrhage. There was a marked abdominal distention, especially below the umbilicus. There seemed to be a vague feeling as of a solid tumor on the right side, but it was not distinct on account of the fluid contents of the abdomen. Vaginal examination showed nothing; the hymen was unruptured. The history was that during menstruation she was suddenly seized with violent colic, which was so severe that she at once sent for her physician, who prescribed a uterine anodyne and stated that he would return. This he did in an hour and found that she had rapidly changed for the worse, and gave symptoms of profuse hemorrhage and severe shock. Dr. Broun saw the patient at this time and she was sent to the Woman's Hospital for immediate operation. On arriving at the hospital her condition seemed to improve and operation was delayed. Her condition steadily improved. One week after multiple fibroids of the uterus largely within the pelvis could be mapped out. The distended condition of the lower part of the abdomen had disappeared. The pulse had become full and normal. On January 9 an abdominal section was performed. Fully a pint and a half of thick blood was found in the abdomen; the amount primarily present was evidently much larger, the watery elements having been absorbed. The blood was present over the entire abdominal contents and was not in any way encystic; it was found in every space and up over the diaphragm. The blood was carefully removed and a search made for the original focus. At the posterior wall of the multiple fibroids of the uterus was an ecchymotic condition of the peritoneal covering of the uterus extending over an area of some two inches in scale. A supravaginal hysterectomy was done. The tubes and ovaries were left, there being no positive evidence of any hemorrhagic focus existing in the pelvis. An incision was made and the entire intestinal tract was submitted to examination with negative findings in every respect except in the mesentery of the appendix. In the location of the appendix was some exudative lymph. On manipulating the mesentery of the appendix a minute opening was found in the vein which passed through the mesentery to the appendix. The patient made an uninterrupted recovery, with the exception of some plastic peritonitis as a result of handling the intestines. This case was reported without any attempt at explanation, since any other than a theoretical one could not be offered. There was, however, an absolute absence of any indication of the hemorrhage having originated from a ruptured corpus luteum. The examination of the urine was negative. The blood pressure was 150.

Carcinoma of the Uterus with Parametric Tissue.—Dr. LeRoy Broun made this report. He said that he presented the specimen on account of its interest and because of the possibility of bringing out a discussion on the present manner of removing as much of the parametric tissue as possible. The patient was 49 years of age, and had had seven children, all with normal labors She presented herself on January 20 with a history of pelvic pain covering a period of four years. She had been having irregular uterine bleeding and her last period was on January 4. Examination showed a bad laceration of the posterior vaginal wall, and bleeding from the uterus was present. Preliminary curettage at the time of the operation gave what was evidently a malignant disease of the uterus situated above the internal os. The radical abdominal operation was performed. The patient's recovery was uninterrupted with the exception of the inability to voluntarily pass her urine for a period of at least three weeks. The pathologist's report showed that the cervical canal, far above the internal orifice, was taken up by friable foreign tissue, which excavated and infiltrated to some extent the cervical. The uterine musculature was hypertrophic and edematous. A vaginal cuff and a large piece of the parametrium were attached to the uterus. The growth had replaced the vaginal portions. There were signs of cauterization on the line of the vagina. The appendages did not show any particular changes. Sections showed strands and solid lobules of a carcinoma composed of regular cells of epithelial origin. Dr. Broun said that the parametric tissue could best be removed by exercising strong downward traction on the uterus, the ureters having been completely isolated. If the Bumm technique was completely followed out the chances of getting out a large amount of parametric tissue was materially added to after the vaginal tube had been cut across. If the Wertheim technique was followed a strong upward traction and the use of the parametric clamp greatly facilitated the removal of the tissue.

Carcinoma of the Appendix.—Dr. Emil Schwartz exhibited a series of slides of appendix carcinoma which showed a few unusual features. The first specimen had been removed by Dr. Pinkham and showed in the gross specimen a thickened tip and a dilated proximal portion. Considerable mucus escaped from the lumen. The serial sections showed that the entire mucous membrane had been destroyed. No traces of Lieberkuehn glands, or crypts, and no lymph follicles could be found. Instead of the normal submucosa there was a dense sclerotic, scarry layer upon which a straight line of high columnar epithelium in a secreting stage was resting. The section further down showed a wavy, high columnar epithelial layer, the cells being arranged in several layers one above another. The tip was solid and contained the plexiform strands of polyhedral cells which were found usually in this form of carcinomatous appendix. The chematic drawing which followed the demonstration of the slides just described illustrated the resemblance of the cells filling the bottom of the Leiberkuehn crypt with those forming the carcinoma. Lubarsch, who first described the so-called small carcinomata of the jejunum, a condition analogous to this form of carcinoma, also showed a similar drawing in order to prove the origin of the carcinoma cells from the Lieberkuehn glands.

Adenomas.—Dr. Schwartz said that this series of slides were remarkable on account of the proliferation of the cervical glands into the uterine musculature as far outward as the serosa peritonei. The musculature in the gross specimen measured about four centimeters in width.

The diffuse hypertrophy of the muscular wall, which resembled an actual tumor, distinguished the adenoma from the adenomyometritis section of Robert Meyer. In spite of this excessive glandular growth and the likeness to the adenoma, these diffuse adenomyomata had to be called benign. This condition was regarded by Recklinghausen as a tumor of the Wolfian body, like other pathological findings in the tube and tumors in the hilus of the ovary. At the present time most of the authors derived these glandular structures from the uterine mucosus glands, and the fact that the cervical glands presented different pictures from those adenomyomata in the region of the corpus uteri, spoke in favor of the latter opinion.

Kruchenberg Tumor.—Dr. Schwartz said that the slide of this tumor was not very satisfactory. The gross specimen presented generally enlarged ovary on one side and an oval ovarian tumor about the size of a cocoanut on the other side. The larger tumor contained a cystic cavity, the contents of which could not be ascertained, since the specimen had been in formalin for years. The sections showed an excessive hypertrophy of the stroma and between the dense strands were numerous large cells, partly single and partly in small plexuses, sometimes arranged like a tubular gland. In certain parts of the tumor were found remnants of ovarian structures. The specimen did not show clearly the characteristic signet ring cells which had been described by Kruchenberg and later by Marchand. Both authors called these secondary tumors, occurring always in both ovaries, fibrosarcoma mucocellulare carcinomatodes. This meant to say that the stroma, which were derived from the ovarian stroma had a sarcomatous character, while the epithelial structures were carcinomatous. The signet ring cells were probably stroma cells, with mucoid degeneration of the cell protoplasm. Their case did not show the clinical signs of carcinoma elsewhere in the body. Professor Schlottlander of Vienna had looked over the slides and had helped them in establishing the diagnosis of this comparatively rare condition.

The "Muscle Operation" for the Repair of Pelvic Floor Lacerations.—Dr. Austin Flint, Jr., said that the fact that so many operations were done for the repair of pelvic floor injuries was proof that the ideal operation had not yet been devised. The object of his paper was to bring before his hearers his present method of operating and to invite discussion and criticism to the end that faults might be discovered and improvements made. In the first place it was necessary to distinguish between operations done for simple lacerations and those done for prolapse, including rectocele and cystocele. It was also important to bear in mind that the vaginal outlet might be closed by this method more tightly than normal and to distinguish between operations done on women who might again become pregnant and those past the menopause. The operation he described was the result of what he took to be the best points in the technique of the various well-known operations. Up to four or five years ago Dr. Flint said that he had used the method of Dr. Studdiford of inserting a buried catgut suture in circular fashion, grasping the muscles on either side and bringing them together in the median line. He now believed that this procedure was faulty, in that the edges of the muscles were not dissected out or as expressed by Sturmdorf, mobilized. Dr. Sturmdorf had beautifully elucidated the principle of deflected pressure by levator interposition, exactly on the same principle that governed the radical cure of ordinary hernia. This principle was carried out in his operation, but the technique was not the same as that used by Dr. Sturmdorf. It might best be described as the Emmet operation, to which was added dissection and mobilization of the levator muscles, their coaptation in the median line by buried sutures and the additional coaptation of the perineal fascia and skin by buried external sutures. This was really a repair in layers. The first step was to outline a triangle by placing a double tenaculum on either side of the reflexed outlet as high as it was desirable to form the new perineum. The apex of the triangle was marked by a double hook or suture placed in the posterior vaginal wall exactly as was done by Emmet. The base of the triangle was then denuded by scissors directly across from the hook on one side to the one on the opposite side. This might be done, if desired, with a knife. The mucous membrane was then grasped by two pairs of forceps at the lower extremities of the sulci bounding the rectocele laterally. Special forceps for this purpose had been designed by Dr. William Ford, his associate, as it was found that the Tait forceps were apt to tear through. Having palpated the edges of the levator muscle, a curved blunt pointed scissors was passed, hugging the vaginal mucous membrane so that it could easily be pushed up in the form of a flap as high as the apex of the triangle and as high on the sides as the points previously marked. With a double hook the muscle itself was then grasped and with the gauze covered finger bluntly dissected anteriorly and posteriorly. At this point it was necessary to use care and gentleness, as the muscle was easily torn and was sometimes imbedded in scar tissue. It should be freed so that it could be brought to the median line without tension. The second step was to suture the muscles together. Kangaroo tendon was best for this purpose, using three sutures in an ordinary case and going anteriorly just far enough to bring the posterior vaginal wall in contact with the anterior. In women past the child-bearing period, especially in cases of cystocele or of procidentia, the muscles were brought together well in front, using four or five sutures if necessary. In young women who might become pregnant care must be used not to bring the muscles too far forward. The sutures were tied just firmly enough to bring the muscles together without tension and the finger in the vagina tested the size of the opening. The third step was to repair the mucous membrane. The triangular flap was trimmed with scissors and the tongue of mucous membrane in the center was drawn down to the outlet. Each sulcus was sewn over a continuous chromic catgut suture exactly as in the Emmet operation. This left only a small external wound, which was brought together so as to include the fascia below the levator muscles. The first suture was of silkworm gut and was passed like the crown suture of Emmet. The remaining sutures might be silkworm gut or chromic gut and might or might not include the already sutured muscles. It took about twenty minutes to perform the entire operation, depending upon the amount of scar tissue binding down the muscles. In cases of complete tears the essential steps were the same, though in his last four cases of complete tears he had made a rectal flap or apron of mucous membrane, dissecting it from above downward as recommended by Ristine, but carrying the original incision outward on the skin to a point just outside of the depression marking the ends of the torn sphincter ani muscle. When this flap was turned down it fell into the rectum and completely protected the sutures from contamination. The retracted ends of the sphincter muscle were picked up with hooks, pulled forward and brought together by buried sutures. The free borders of the levator might then be found, mobilized and sutured as in a simple tear. This technique seemed to be rational and surgical in its principles and gave ideal results, both immediate and remote.

Dr. Arnold Sturmdorf said that as a promoter of direct levator myorrhaphy in perineal repair, he could but express his gratification and appreciation of Dr. Flint's graphic corroboration of his former contention. He said that he must, however, maintain that the removal of the vaginal flap was unnecessary and even undesirable, inasmuch as the mucosa was merely relaxed, not superabundant and its removal converted the normally rugous vaginal channel into an abnormally smooth walled canal. The correct management of the elevated vaginal flap, adapting it correctly over the adjacent denuded surfaces according to the technique described in his publications, removed all appearance of superabundant tissue. He would also object to the use of scissors in mobilizing the levator bundles; the finger more readily isolated the normal lines of cleavage between the muscle and its surroundings, thus avoiding mutilation and injury to the branches of the internal pudic artery and in certain cases to the hemorrhoidal sinuses. These, however, were only questions of individual practice, the recognition of the levator function and its restoration being the main consideration.

The Value of More Accurate Diagnosis in Gynecology.—Dr. Edward W. Pinkham read this paper. He said that he had been making an inquiry into the relation of the diagnosis to the results in his cases for a period of five years. During that time he had been surprised to find how often he had corrected an anatomical deformity or removed a certain lesion without eliminating the symptom for which the patient sought relief. He had endeavored to find the reason for his failures. His first discovery was that histories and clinical data were not only too meager but entirely too general in character. This he thought was a common fault. It was one that could easily be corrected. As a result of his reflections on this subject he had made it a habit, after recording the patient's own version of her symptoms, to take each symptom in order and to elaborate it to the fullest extent. Since he had begun this practice his diagnosis had been more nearly correct than formerly and his operative results had proven the wisdom of his course. He believed that the crying

need of both hospital and private work was a more systematic and searching personal history, together with more general clinical data. By the latter he meant that as a matter of routine all the important organs, heart, lungs, stomach, intestines, etc., should be examined as well as the blood and urine. A test for indican was important and the thyroid and ductless glands should not be overlooked. A second discovery that he had made was that his conception of the cause of pain, the symptom most generally complained of, and for which relief was sought, was rather vague and without any clear pathological basis. The textbook teaching regarding the etiology of pain was very indefinite and writers made vague and unsatisfactory statements. He ventured the opinion that pain was usually caused by overdistention of an organ or structure, it might be by blood, serum, pus, or other substance. The chronic pain was due to a chronic infiltration or overdistention. Irritation and motion increased pain and increased the distention. This theory had enabled him to distinguish between the pain of an acute hyperemia of the ovary and that of a salpingitis or a varicosity and passive congestion of the pelvic plexuses and veins from chronic ovaritis. This had taught him that when pain was referred to a certain locality, that almost invariably the offending lesion was situated at that locality or in the immediate vicinity, thus excluding to a large extent the idea of reflex pain. The third discovery that the author had made in his examination of the records was that he had fallen into the habit, which he thought was more common among general practitioners than among specialists, of associating the pelvic organs with almost any symptom for which a woman sought relief. Dr. Pinkham said that since he had been applying these principles he was positive that fewer of his patients had wandered into the hands of other surgeons seeking the relief which he had failed to give.

A Comparative Study of Two Advanced Cases of Cancer of the Cervix Uteri.—Dr. Dougal Bissell read this paper. He said that he had reported these two cases because of the widespread demand, when this stage of the disease was encountered, for the removal of the uterus, its adnexa, and adjacent tissues. These cases were reported with the feeling that records of concrete cases were of value in determining not only the most satisfactory basis for generalization, but were helpful in determining the question of operability or inoperability in a given case. The first case was that of a woman 46 years of age, having a vaginal discharge, bloody, offensive, and somewhat irritating and an extensive erosion of the cervix and vaginal mucous membrane. There was a thickening of the parametric tissues with consequent fixation of the cervix. The diagnosis of cancer of the cervix was made and an operation performed. The patient recovered and remained in good health for eight months. Examination showed the vagina only one and one-half inch in depth with hard and thickened walls. The patient soon began to fall rapidly. Vomiting and anorexia were so persistent that it was decided to give relief by doing a gastroenterostomy, though it was appreciated that death was inevitable. She survived this operation only a few days. The post mortem showed pyonephrosis, hydronephrosis, carcinoma of the cervix uteri, and metastases in the diaphragm and mesenteric nodes. There was an atrophic left kidney with compensatory hypertrophy of the right kidney and multiple abscesses and fatty degeneration of the liver. The second patient was 47 years of age and menstruation had been normal until three months previous, since which time she had had a slight bloody discharge, not offensive. She had pain in the lower abdominal region and back, radiating down the hips, loss of weight, and marked anemia. There was a trace of albumin in the urine, but no casts. There was a growth from the right side of the cervix extending into the parametric tissue. The fundus was movable. A circular incision was made about the vaginal portion of the cervix and at a considerable distance from it. The vaginal mucous membrane was dissected from its adjacent tissue and an inch or more removed. The growth on the right side was so extensive that it was necessary to open the abdomen in order to intelligently complete the operation. The bladder was found firmly adherent to the anterior surface of the cervix, and a large portion of it had to be removed. The bladder wound opened completely on removing the gauze and the bladder and vagina formed a continuous tract so that the mouth of each ureter could be distinctly seen in the lateral angles. Repair was attempted after seven weeks. The pathologist reported that the specimen removed at the first operation was "squamous celled carcinoma of the cervix." The growth was very extensive, and quite typical. The pathologist further stated that the growth was one of the largest cervical cancers that he had ever seen successfully removed. The patient was discharged from the hospital on June 6, 1912, and died August 5 of the same year. The first case was one typical of a class possessing unquestionable evidence of advanced malignant lesion, yet a class to which radical operation was not infrequently applied. In the light of knowledge gained from personal experience it seemed to him beyond the hope of surgical cure. So with the idea of choking the rapidity of the growth and ameliorating some of the local symptoms, the cautery and caustics were applied. Out of the eleven months that she lived eight of them were spent in comparative comfort. He was of the opinion that radical operation would only have exposed the patient to greater risk of immediate death and would have offered no hope of ultimate recovery. A more radical operation could hardly have been performed than was done in the second case. Retrospectively it semed to him that the surgical result in this unpromising case was better than he had reason to hope, yet the disease was not checked. In fact, the operation only jeopardized the patient's life and offered grave chances of added complications, equally, if not more distressing, than were the original symptoms. In the early stages of cancer all surgeons were in accord in regarding the advisability of one of the several radical procedures now in vogue, but the combined experience of the surgical world had not yet determined the line of demarcation between operable and inoperable cases. In the experience of the writer when malignancy had practically destroyed the cervix and had involved the vaginal mucosa or adjacent tissues, metastases, with few exceptions, had begun to form and the disease was beyond the reach of the knife.

Malted Food in Treatment of Enteritis.—Solon Veras begins the treatment of a case of enteritis with a water diet, sometimes continuing with vegetable broth, and then very rapidly reached the malt soup stage. But instead of at once resorting to malt soup prepared with milk, he starts with malt soup prepared with pure water, employing 900 grams to a liter of water, instead of 600 grams of water and 300 grams of milk. The following day he gives malt soup prepared with milk, alternating each meal with malt soup without milk. Tolerance to milk becomes established and never offers any difficulty.—*British Journal of Diseases of Children.*

Ankle-Clonus Without Gross Disease of the Nervous System.—Wilder Tileston concludes that ankle-clonus indistinguishable from the genuine may be found more or less frequently in a variety of conditions, without accompanying organic nervous disease. These conditions are: (*a*) Acute infectious diseases, especially typhoid; (*b*) chronic infections associated with marked toxemia, especially tuberculosis of the lungs in the third stage; (*c*) uremia shortly before and during the acute uremic seizure; (*d*) epilepsy immediately after the convulsion; (*e*) intoxication from certain drugs, *e.g.* hyoscine, ether, and chloroform; (*f*) excessive fatigue; (*g*) exceptional cases of certain neuroses, viz., neurasthenia, hysteria, paralysis agitans; (*h*) psychoses in the stage of excitement; (*i*) chronic articular rheumatism. With the exception of joint disease, a toxic action on the nervous system may be assumed in all these states as the underlying factor in the production of clonus. This is obvious in the case of the infectious diseases and drug intoxications; in uremia, epilepsy, and undue fatigue the presence of toxic products of metabolism may be regarded as probable, though not yet demonstrated, and even in hysteria and neurasthenia the action of toxic products in severe cases cannot be excluded. In the case of articular rheumatism a constant spinal irritation from the inflamed joint tissues is the probable cause. In two autopsies on cases of phthisis, with clonus, no changes were found in the central nervous system. In the author's case, however, inflammatory exudate was demonstrated about the posterior median artery in the posterior septum of the bulb. Clonus due to toxic states usually may be distinguished from that of organic nervous disease by the absence of spasticity and of other signs pointing to organic disease, and particularly by the absence of the Babinski and Oppenheim toe signs. An exception to the above rule is encountered after the use of hyoscine in medicinal doses and immediately after the epileptic attack, in both of which instances the Babinski and Oppenheim signs may be positive. The occurrence of ankle-clonus is of prognostic value in uremia, preceding at times the acute seizure. Ankle-clonus usually disappears a few days before death, otherwise its disappearance usually indicates an improvement in the patient's condition.—*American Journal of the Medical Sciences.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MANUAL OF TROPICAL MEDICINE. By ALDO CASTELLANI, M.D., and ALBERT J. CHALMERS, M.D., F.R.C.S., D.P.H. Second edition. Cloth; price, $9 net; illustrated, 1,747 pages. William Wood & Company.

TEXT-BOOK OF ANATOMY AND PHYSIOLOGY FOR NURSES. By AMY E. POPE. Illustrated; cloth; price $1.75 net; 554 pages. G. P. Putnam's Sons, New York and London.

INDUSTRIAL POISONING. By Dr. J. RAMBOUSEK. Translated and Edited by THOMAS M. LEGGE, M.D., D.P.H. Illustrated; cloth; price $3.50 net; 300 pages. Longmans, Green & Company, New York.

GOUT, ITS ETIOLOGY, PATHOLOGY AND TREATMENT. By JAMES LINDSAY, M.D., M.R.C.P.; cloth; price $1.50; illustrated; 212 pages. Oxford University Press, London.

TUBERCULIN TREATMENT. By OLIVE RIVIERE, M.D., F.R.C.P., and EGBERT MORLAND, M.B. & B.Sc., M.D. Second Edition. Cloth; price $2.00; 247 pages. Oxford University Press, London.

A MANUAL OF VENEREAL DISEASES. By Various Authors. Second Edition. Revised and Largely Rewritten. Cloth; price $3.75; illustrated; 318 pages. Oxford University Press, London.

SKIN DISEASES IN GENERAL PRACTICE. By HALDIN DAVIS, M.B., B.Ch., B.A., F.R.C.S., M.R.C.P. Illustrated; cloth; price $3.75; 340 pages. Oxford University Press, London.

MANUAL OF OBSTETRICS. By JOHN OSBORN POLAK, M.Sc., M.D. Illustrated; leather; 468 pages. D. Appleton & Company, New York.

TWENTY-THIRD ANNUAL REPORT OF THE EYE, EAR, NOSE AND THROAT HOSPITAL OF NEW ORLEANS, LA., January 1, 1912, to December 31, 1912. Paper; 78 pages. Palfrey-Rodd-Pursell Co., Ltd., New Orleans.

JOHN BARLEYCORN. By JACK LONDON. Illustrated; cloth; 343 pages; price $1.30 net. The Century Company, New York.

OLD AGE. By ROBERT SAUNDBY, M.D.; cloth; price $2.10 net; 312 pages. Longmans, Green & Company, London.

MANUAL OF OPERATIVE SURGERY. By JOHN FAIRBAIRN BINNIE, A.M., C.M. Sixth Edition. Revised and enlarged; illustrated; cloth; price $7.00 net; 1251 pages. F. Blakiston's Son & Company, Philadelphia.

MECHANICAL TREATMENT OF ABDOMINAL HERNIA. By WILLIAM BURTON DEGARMO, M.D. Cloth; price $1.50; illustrated; 147 pages. J. B. Lippincott Company.

AGRICULTURAL BACTERIOLOGY. By F. LOHNIS, Ph.D. Illustrated; cloth; 136 pages. Charles Griffin & Company, Ltd., London; J. B. Lippincott Company, Philadelphia.

MARRIAGE AND GENETICS. By CHARLES A. L. REED, M.D., F.C.S. Cloth; price $1; 183 pages. The Galton Press, Cincinnati, Ohio.

BEITRÄGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITÄTSFORSCHUNG. By Prof. Dr. L. BRAUER. Volume 1, Part 3; paper; price 6 m.; illustrated. Curt Kabitzsch, Wurzburg.

PEDIATRICS. Edited by ISAAC A. ABT., M.D. Volume 5. The Practical Medicine Series. ORTHOPEDIC SURGERY. Edited by JOHN RIDLON, A.M., M.D., with the colaboration of CHARLES A. PARKER, M.D. Cloth; price $1.35; illustrated; 235 pages. The Year Book Publishers, Chicago.

PROCEEDINGS OF THE MENTAL HYGIENE CONFERENCE AND EXHIBIT, at the College of The City of New York, November 8-15, 1912. Paper; 224 pages. Published by the Committee on Mental Hygiene of the State Charities Aid Association, New York.

TRAITEMENT DE LA SYPHILIS. Par le Serum Organique du Dr. L. C. QUERY. Paper; price 2 f.; illustrated; 78 pages. Laboratoire de Serotherapie Specifique et de Microbiologie, Paris.

THERAPEUTIC CLINIQUE DES MALADIES DE L'ESTOMAC ET DES SYMPTOMES ASSOCIES. Paper; price 6 f.; 274 pages. Maloine, Editeur, Paris.

DIE UNTERSUCHUNG DER LUFTWEGE. By Dr. P. H. GERBER. Paper; illustrated; 45 pages; price 2 m. Curt Kabitzsch, Wurzburg.

PRACTICAL BACTERIOLOGY, BLOOD WORK AND ANIMAL PARASITOLOGY. By E. R. STITT, A.B., Ph.G., M.D. Third Edition. Revised and Enlarged; illustrated; cloth; price $1.50 net; 408 pages. P. Blakiston's Son & Company, Philadelphia.

Miscellany.

The "Senior Surgeon's" Troubles.—In "The White Linen Nurse," a story in which Eleanor Hallowell Abbott relates in witty vein how "Rae Malgregor undertook general heartwork for a family of two," the "Senior Surgeon" loses control of his automobile while on a trip into the country where he has been summoned to attend an urgent case. The nurse, who accompanies him, finally succeeds in extricating him from under the wreck of his car. These are a few of his reflections as, couched on the ground in a neighboring field, he watches the flames devour the remains of his high-priced automobile:

"The Senior Surgeon's nostrils were all puckered up with the stench of burning varnish. The Senior Surgeon's mind was full of the horrid thought that he'd forgotten to renew his automobile fire insurance, and that he had a sprained back, and that his rival colleague had told him he didn't know how to run an auto, anyway, and that the cook had given notice that morning, and that he had a sprained back, and that the moths had gnawed the knees out of his new dress-suit, and that the superintendent of nurses had had the audacity to send him a bunch of pink roses for his birthday, and that the boiler in the kitchen leaked, and that he had to go to Philadelphia the next day to read a paper on "Surgical Methods at the Battle of Waterloo," and he hadn't even begun the paper yet, and that he had a sprained back, and that the wall paper in his library hung in shreds and tatters, waiting for him to decide between a French fresco effect and an early English paneling, and that his little daughter was growing up in wanton ugliness under the care of coarse, indifferent hirelings, and that the laundry robbed him weekly of at least five socks, and that it would cost him fully seven thousand dollars to replace this car, and that he had a sprained back."

A Suggestion for the Doctor's Waiting Room.—The literature, which the busy physician provides for his waiting patients, reflects at once the physician's own taste and the character of his clientèle. A few high-class and recent magazines are far better than a host of cheap periodicals. The average layman is not slow to judge a physician by the character of reading matter which he provides for the patients. A further hint along this line may be of some service. The covers of magazines, after a day or two of use, are usually torn at the edges, badly crushed, and soiled. When the magazine is new, if the cover and the adjoining three or four advertising pages are pasted together, the result will be a firm and durable cover.

The Late Dr. Billings.—At the memorial meeting, held in honor of Dr. Billings, S. Weir Mitchell recalled how the latter, when asked about the number of degrees he had received started to count the LL.D.'s and B.C.L.'s, and then laughingly said: "Yes; that is my principal title to be considered a man of letters." Richard R. Bowker told of a visit paid by Billings to the private library of Oliver Wendell Holmes, who related how Dr. Billings made tracks for the most valuable books on the shelves. "Why, sir," said Holmes, "Dr. Billings is a bibliophile of such eminence that I regard him as a positive danger to the owner of a library if he is ever let loose in it alone."

COLLICULITIS, OR DISEASE OF THE VERUMONTANUM.

By ABR. L. WOLBARST, M.D.,

NEW YORK.

CONSULTING GENITOURINARY SURGEON, CENTRAL ISLIP STATE HOSPITAL; GENITOURINARY SURGEON, PEOPLE'S HOSPITAL, WEST SIDE GERMAN DISPENSARY AND HOSPITAL, AND BETH ISRAEL HOSPITAL DISPENSABY, ETC.

In many of the text-books, not yet considered old, the verumontanum or colliculus is mentioned as a more or less vague and indefinite ridge or elevation on the floor of the posterior urethra; little or nothing is said about its physiology, except that it is thought to be the seat of sexual feeling, and about its histology and pathology, practically nothing. However, with the development and perfection of the posterior urethroscope, all of this has been changed. The pictures of the colliculus, both in the normal and pathological conditions, are indeed a revelation as showing the marked difference between the stereotyped text-book conception of an organ obtained on the dissecting table, and the organ itself as seen with the aid of artificial illumination and slight magnification. And it is a matter of further interest that some of the more recent text-books on genitourinary diseases still present that ancient picture of the colliculus, a picture that no one has ever seen through a urethroscope.

To describe the normal colliculus would be rather difficult, for there is no fixed type or form of the organ. As a matter of fact its appearance on examination depends in a great measure on the type of examining instrument used. Examine the colliculus with a simple straight or curved tube and compare the picture with that seen through one of the later types of instrument. The difference is very striking. With the simple tube the colliculus is seen (though sometimes it cannot be seen at all) as a small swelling, rather poorly illuminated and protruding into the posterior urethra like a small red pea (Fig. 1). A positive diagnosis based on such a picture is next to impossible. With the newer instruments,* however, the colliculus is seen as a distinct, well-lighted projection from the floor of the urethra into the urinary canal. Generally it

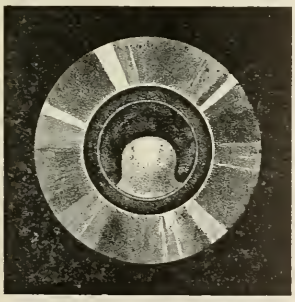

Fig. 1.—Colliculus seen with a simple straight or curved tube.

Fig. 2.—Dome-shaped colliculus, with utricle situated at the apex.

may be said to resemble an enlarged glans clitoris, or in some cases it resembles a small cherry or strawberry. Sometimes it assumes a domelike shape, with the opening of the utricle situated at the pointed or flattened summit (Fig. 2); often it resembles a cone, the walls rising and meeting sharply in a pointed peak (Fig. 3); occasionally the peak is flattened as if the apex were sawed off (Fig. 4); again it may assume a rounded bulbous shape, resembling a spherical door knob or an electric bulb (Fig. 5). Whatever its shape may be in the normal condition, the general outline remains pretty much the same in disease, except that the smooth walls may become turgid and roughened or replaced by corrugations, excrescences or cysts of distinctly inflammatory origin (Fig. 6).

As a rule the utricle is placed at the summit of the colliculus, flanked on either side by the ejaculatory ducts. There are exceptions to this rule, and they are found very often. The utricle may be seen on the anterior wall or even on the posterior wall, and the ejaculatory ducts may be observed near the summit or adjacent to the base. Not infrequently tortuous blood vessels may be seen, crossing the anterior wall from side to side, or mounting the anterior aspect, only to disappear in the mucous membrane of the urethral wall. The sloping of the walls of the colliculus attracts our attention by its variations. Generally the walls slope gradually and gracefully downward and laterally, forming a concave trough-like lateral sulcus, be-

*By far the best instrument for this purpose is the cystourethroscope, made by Wappler, of New York, and devised by Dr. Leo Buerger, while a member of the writer's staff, at the West Side German Dispensary and Hospital, N. Y.

yond which rises in an unbroken and continuous curve the lateral wall of the urethra (Fig. 5). On the other hand, the lateral sulcus may appear in the shape of a deep, narrow trench, created by the sharp junction of the apposing walls of the colliculus and the urethra. In these cases, we find the

Fig. 3.—Cone-shaped colliculus with utricle situated on the anterior aspect near the apex

prostatic ducts, from three to six or more in number, long and narrow, with the appearance of deep slits (Fig. 4). When these apparent slits are probed carefully it will be found that they look deeper than they really are; this is due, in all probability, to variations in the illumination and the development of shadows.

Though the organ is firmly fixed on its broad base, it is capable of considerable movement to and fro and from side to side. This is seen very beautifully when the irrigation fluid is turned on and off suddenly. With the water flowing at a brisk pace the colliculus will be seen to move perceptibly in response to the impulse of the stream and the lateral sulci become wider and more distinct as the fluid compels the outward bulging of the lateral urethral walls. And when the current is turned off suddenly it will rebound to its former position. In this manner, by turning the stream of water on and off suddenly and repeatedly, a much better view of the organ in its various aspects can be obtained than is otherwise possible.

We are not yet sufficiently acquainted with the colliculus and its pathology to state in detail all the ills to which it is subject. We may safely say, however, that the most common pathological condition of this organ with which we have to deal is the inflammatory process following or coincident with a gonococcus infection of the deep urethra and prostate. In the past, owing to our lack of facilities for the examination and study of the colliculus, we were justified in considering the prostate as the site of predilection for chronic gonococcus infection of the deep urethra. It would be manifestly improper, in view of our increased knowledge of the subject, to maintain this attitude today without considerable modification. Such a diagnosis cannot be made today without a careful examination of the colliculus by means of a posterior urethroscope of modern type. It must be a common experience, as it has been that of the writer, to find a distinct pathological lesion in the colliculus, while the treatment has been persistently and uselessly directed at the prostate or seminal vesicles, or both. The writer knows of a case in which the seminal vesicles were removed after the method of Fuller, with but little benefit. In this case two small cysts were found impinging on the anterior wall of the colliculus. When these were ruptured and their base cauterized with silver nitrate the relief was almost instantaneous. It is apparent that an examination of the deep urethra with the urethroscope would undoubtedly have spared the patient the ordeal of Fuller's heroic operation. In many of these cases dilatation of the posterior urethra, prostatic massage, irrigations and instillations have been given to the utmost limit of the patience of both the patient and the surgeon, all without the slightest benefit, and all due to the fact that the correct diagnosis was not made.

Consequently it becomes our duty as a matter of routine to examine the colliculus in every case of chronic urethritis, particularly those cases in which the usual treatment of the prostate and seminal vesicles has not relieved the patient. If this policy is adopted we will be surprised at the large number of cases with faulty diagnosis which will be revealed. I do not now recall anything more striking in this connection than the following case:

J. L.—Complained of a continuous sense of burning and heat in the perineum and radiating occasionally to the meatus. His physician had dilated his deep urethra up, to 45 French; he had used all the old and many of the new methods of treatment and finally decided that he was dealing with a case of sexual neurasthenia and that there was nothing further to be done with him. When I saw him the man was greatly worried about his condition, and he almost believed the physician who declared that he was a neurasthenic and that nothing would ever relieve him. On examination (March, 1910), I found a red, turgid colliculus, much larger than normal, and bleeding easily when touched with the instrument or cotton carrier. On its right wall was a large cyst, by far the largest I have ever seen (Fig. 7). It was fully one and a half inches in length and one-quarter inch in diameter, shaped like a sausage and twisted on itself like a bow-knot. On the left posterior wall, near the base, was a much smaller cyst, about the size of a bean. The cysts were first punctured giving forth a serum-like fluid, and as much as possible of their thin walls was removed through the fenestra of the urethroscope. After a number of local applications of silver nitrate (10 per cent.), the patient was relieved of his symptoms, which had lasted fully eight years.

It is evident that the colliculus must suffer involvement in practically every case of posterior gonococcal urethritis; this is particularly important to remember in connection with the frequency of involvement of the ejaculatory ducts and pros-

Fig. 4.—Colliculus with flat top utricle situated on the anterior aspect. Note ejaculatory ducts in the lateral sulcus

tatic sinuses. Hence we must not be surprised to find inflammatory conditions of the colliculus in cases of premature ejaculation, sexual impotence, sterility, and the male neuroses. Whether the inflammation of the colliculus is the cause of the disturbances in the sexual system, or merely the effect

of the genital disturbance, is still an interesting mooted question. Quite likely the colliculus is a far greater factor in the physiology of the sexual function than we are prone to believe, and it is not difficult to see that a gonococcus infection involving this organ must have an appreciable effect on

Fig. 5.—Doorknob, or bulb-shaped colliculus. Compare with Fig. 1. Note the slight magnification and greater illumination obtained with the cystourethroscope.

the entire genital economy. It is, therefore, imperative to suspect the presence of disease of the colliculus in every case of sexual disturbance, particularly when it has been preceded by a gonococcus inflammation or a history of excessive sexual abuse. A careful urethroscopic examination of the posterior urethra and the colliculus is, therefore, demanded in every case presenting sexual disturbances.

The urinary function is also involved to a greater or less degree when the colliculus is subject to inflammation. I have seen an instance of terminal hematuria with painful micturition, which lasted several months, and resisted every method of treatment, until the colliculus was examined and treatment directed to that organ. In this particular case there was a decidedly granular area on the anterior aspect of the colliculus just below the summit, which bled profusely when touched ever so slightly. However, under repeated local applications of adrenalin and silver nitrate through the posterior urethroscope, the bleeding and pain stopped and have not returned.

It is well to remember, even though this be a

Fig. 6.—Colliculus almost covered with small cysts. Utricle situated at the apex.

repetition, that the colliculus may be the seat of the inflammatory process, and the prostate as a whole may appear to be entirely normal; nevertheless, such a congested and inflamed colliculus may be responsible for a series of symptoms which cannot be differentiated from those associated with typical prostatitis, except by means of the urethroscope. As has already been intimated, inflammation of the colliculus is not always of gonococcus origin necessarily, any more than such is the case with chronic prostatitis; any continuous and persistent irritation involving the sexual function may be responsible for the development of the inflammatory process. Among these the principal causes are bad sexual habits, coitus interruptus or withdrawal, frequent and excessive masturbation, and persistent excitement without gratification. Fortunately, colliculitis due to any of these causes responds quite readily to local treatment applied through the urethroscope.

Defecation spermatorrhea, a very common complaint, is usually ascribed to the existence of a chronic inflammation of the prostate. In a case which I had the opportunity to study, I found no evidence of prostatitis, but the colliculus was enlarged, turgid and congested; the spermatorrhea made a rapid disappearance after a course of treatment of the colliculus without any treatment of the prostate.

Treatment of the colliculus consists almost entirely in the application of silver nitrate to the organ through the posterior urethroscope. I pre-

Fig. 7.—Unusually large cyst projecting from the anterior wall of the colliculus. A small cyst is seen on the posterior wall.

fer a 10 per cent. solution, applied with a cotton carrier; a 20 per cent. solution is often recommended, and I have known instances in which the pure silver stick has been employed. I believe there is no advantage to be obtained in the use of solutions of such great strengths, and that the reaction is sometimes too great to be of any service to the patient.

Similarly with tincture of iodine; while it may be effective in weak solution, it is altogether too irritant in full strength, and the reaction which follows such an application is often so great that patients justly refuse a second treatment. Bleeding, urinary strangury, and tenesmus, and even complete retention of urine have followed these strong applications of silver and iodine. The galvanocautery may be used with benefit, and the Oudin high-frequency current likewise. The latter is particularly indicated in the presence of cystic and papillomatous growths, and also for the "fulguration" of dilated ducts and glands. Applications should be made at rather infrequent intervals, as we must allow for the passing off of the reaction which always follows. An interval of from four to seven days appears to me the most satisfactory and beneficial.

113 East Nineteenth Street.

VENEREAL PROPHYLAXIS—PAST AND PRESENT*

By SURGEON ROBT. A. BACHMAN, U. S. N.,

U. S. S. "DELAWARE."

Syphilis probably existed in Europe before the discovery of America but it is quite probable also that the disease was not so prevalent and that the coincidence of its increased dissemination with the voyage of Columbus gave rise to the frequently accepted idea as to its American origin. In 1495 A. D. an epidemic of syphilis occurred in the French army which was fighting against the Kingdom of Naples and the disease spread all over Europe. Gonorrhea was up to the time that Ricord made the distinction, frequently considered the same and confused with syphilis. In fact, not until Neisser's discovery in 1879 was the line scientifically drawn. The same is true of chancroid, which was included in Ricord's classification made in the middle of the last century. Ducrey's discovery of the bacillus bearing his name helped further in the elucidation.

It will be seen from this that efforts to combat venereal diseases in the early ages were not in reality employed against any one disease but rather against venereal infection in general, against what was then thought to be syphilis. Thus the celebrated Venetian physician, Nikolaus Massa, in his book "De Morbo Gallico," recommended postcoital washings with white wine or vinegar in 1532. Frakoster indicated the use of lemon juice. Petronius used a mixture of wine of camphor and urine in 1564.

Rauchin sprung an innovation by advocating the application of plasters melted by warming, before intercourse. Professor Ettmueller of Leipzig, in 1690, mixed white wine and turpentine in the hopes that it would do some good. It would hardly be a popular mixture today. Palmarius believed in the efficiency of guaiac and wine. The general trend of opinion seems to have inclined towards wine and acids, foreshadowing the antiseptic value of alcohol which is still reflected in the widespread use of whiskey at the present time.

In 1733, Desault anticipated the rest of the world some 170 years by declaring that syphilis was caused by small invisible worms which were "deleteriously influenced" by the ingestion of mercury. He reasoned therefore that mercury applied locally in the shape of salves had a preventative action. Mahon in 1770 tried to introduce washings with alum. Warren in England spoke for astringents before coitus and alkaline injections afterwards, a procedure that received Hunter's recommendation. But Hunter also advised the use of warm solutions of bichloride of mercury in water. Malpert, too, believed in these solutions.

A secret prophylactic was brought out by Luna Calderon in 1812. He carried his secret to the grave and has an important place in the history of prophylaxis only because he was the first one to recognize the value of direct evidence in dealing with the subject. To this end he experimented on himself, making an inoculation which seemed to have proven his claim. The unprotected control developed a soft chancre whereas Calderon thought he was dealing with lues. This does not change the value of his experiment particularly as far as its lesson in the substantiation of claims goes.

*Read by invitation before the annual meeting of the Rhode Island State Medical Society, June 5, 1913.

Langlebert too, in 1851 made an experiment with potassium soap and oil of citron in which he inoculated a man and left a control unprotected. The result was a success but the development of a sore the day following, at the site of the control, makes it likely that the infection again was chancroidal.

In the era of antiseptics the list of substances used, and the men recommending them, is too great to permit of their classification. On the whole the choice is largely in favor of mercury bichloride and the other mercury salts. Finally at the end of the century the precursors of our modern methods begin to appear. It is very interesting to watch this gradual development, like a blindfolded child getting closer to the hidden object it seeks. Behrman advocates gray salve, Feibes the salicylate of mercury in mucoid solution, Grosse made up a combination of mercury oxycyanide and gelatin and glycerin, all these combinations being devised against syphilis.

Then further improvement began to be manifested. Richter produced his "salve candles" composed of gray ointment reinforced by ¼ of 1 per cent. resorcin. This comes pretty close in principle to the latest formulas in use now. Against gonorrhea especially, Uhl and Schulze favored a 1 per cent. formalin in wax salve, and Zemmer changed the ordinary methods entirely by making vaginal suppositories of small percentages of chinosol, urotropin, and benzoic acid in a saponaceous base, these to be used before coitus. It might be well to mention here too that Neisser advised the use of simple fatty inunctions before intercourse as a preventative.

All these efforts to reduce the occurrence of venereal diseases were attended by a considerable lack of statistical data and experimental support. Suddenly the entire aspect of the question changed when Metchnikoff announced his discovery that syphilis was communicable to apes and later that this infection could be prevented if a 33 1-3 per cent. salve were rubbed into the site of inoculation. His experiments not only included calomel but other mercury preparations such as the salicylate and ammoniate, but the results obtained with calomel proved the most satisfactory. Following this came his well known experiment upon the then medical student, Maisonneuve, which led the latter to say later, "it is indisputable that the employment of calomel salve by the individual will prevent the occurrence of syphilis." Contrary to the general belief in this country this announcement was not accepted in Europe without challenge. Neisser at first objected on purely theoretical grounds and later before the Congress of Dermatology at Berne he described some failures he had had in producing immunity in monkeys. Metchnikoff objected to this on the grounds that a 10 per cent. salve had been used, whereas he had recommended 33 1-3 per cent. This objection seems entirely valid and I have suggested in the *Journal of the American Medical Association* that this might easily account in part for the failures that have occurred in this country.

Gaucher, the eminent syphilologist of the St. Louis Hospital in Paris, stated his disbelief and reported two cases from his observation where infection followed in spite of the calomel salve used as per instructions. But Gaucher is a medical agnostic and does not believe in many things that are considered as of value by other authorities which is shown for example in his attitude towards sal-

varsan which he never administers. The question of determining a failure for a prophylaxis is hard indeed because so many things have to be considered, and I believe too that the most enthusiastic believers in venereal prophylaxis will not deny the possibility of an occasional failure. For instance, it is quite conceivable that a man after a prolonged coitus during which he has chafed himself sore to a considerable extent and absorption has taken place, should become infected, especially if the subsequent prophylactic inunction was delayed or not thoroughly carried out. Consistent laboratory efficiency is a proof, exactly observed, that can not be thrown aside for an occasional practical failure where the conditions are not subjected to the same scientific scrutiny.

Siebert made an exhaustive study of all chemicals that might have an antiluetic action. His work represents the latest information. He not only repeated the experiments of Metchnikoff but tried various modifications of the same. His first series were made with a virus attenuated by mixing it and the chemical to be tested. Potassium iodide and solutions of corrosive sublimate in greater than 1-10,000 strength proved of no value. Atoxyl, calomel and stronger solutions of mercury bichloride were effective. When the virus, which consisted of a paste made from the bone marrow, spleen, and liver of luetic apes, was left unattenuated and the test substance was applied to the vaccination, the results were slightly different. Two out of three attempts with corrosive sublimate 1-1000 failed after an hour's interval, four attempts with 10 per cent. calomel failed also. Four with 1-500 corrosive sublimate, two with 33 1-3 per cent calomel, three with 5 per cent. silver nitrate, and two, where the application was delayed 24 hours, using 1-500 corrosive sublimate in 20 per cent. glycerin, were all successful. The vaccinations were all done above the eyebrows of apes. Siebert also made further experiments using a combination which he considers better than calomel salve—a combination of starch, tragacanth and gelatin and corrosive sublimate in the strength of 1-500. This ointment applied no longer than fifteen minutes after, yielded one failure out of eleven inoculations. After Siebert, Schereschewsky reported seven inoculations which were treated with chinin salve and gave negative results. Controls left untreated on the opposite eyebrow developed primary lesions.

Siebert concludes that calomel salve is valuable but that the antiseptic power of calomel is reduced by being placed in a fatty base. He cites Koch to the effect that fats destroy the potency of carbolic acid and that his own experiments show this to be the case with calomel. His results with the starch-tragacanth-gelatin paste are not very convincing, especially in the light of Metchnikoff's later experiments where thirty inoculations gave thirty successful preventions.

In the United States the stimulus received from the work abroad was felt primarily, as would naturally be expected, in the branches of our military force. Individual efforts to protect enlisted men from the damages produced by venereal infection were begun about 1906. In the Army, Raymond was among the first to introduce a system of prophylaxis. He made up a package containing an eye dropper and argyrol solution which was intended to combat gonorrhea; later he added calomel ointment. The scheme was too complicated to be successful from a practical point of view. In the Navy the double method was adopted from the first. This method depended upon giving the admittedly exposed man upon his return to the ship the next morning, antigonococcic injections followed by inunctions of calomel ointment. This procedure was also carried out in the Army shortly after. Modified slightly with educational features added, it was officially adopted in the Navy in 1908 and in the Army in 1909.

A period of activity followed. Reports began to appear. Results mostly favorable, saw the light of print. Physicians in civil life began to take notice receiving the impression that the work in our two services had solved the problem. Then changes in formulas began to crop out, some dissatisfaction became manifested, the figures of the annual statistical reports of the Surgeons-General were compared and no diminution in the yearly admission rates could be seen. The explanation was that the increased interest in the subject had resulted in closer inspection of the men which in turn had resulted in a greater number of cases being brought to light that formerly had gone unreported. This was undoubtedly true and answered adverse criticism for a while but more yearly reports came out and still no decrease occurred. It was reasonable to suppose that after several years the number of cases brought to light each year over the year previous had to reach a limit and could not keep pace with the decrease that enthusiastic individual reports claimed for prophylaxis. The figures for the Army are as follows:

Gonorrhea—		
1905	118	per 1000
1906	105	per 1000
1907	107	per 1000
1908	123	per 1000
1909	125	per 1000
1910	102	per 1000
1911	94	per 1000
Chancroid—		
1905	20	per 1000
1906	26	per 1000
1907	34	per 1000
1908	28	per 1000
1909	25	per 1000
1910	26	per 1000
1911	25	per 1000
Syphilis—		
1905	30	per 1000
1906	27	per 1000
1907	25	per 1000
1908	23	per 1000
1909	26	per 1000
1910	26	per 1000
1911	44	per 1000
Total venereal—		
1905	178	per 1000
1906	158	per 1000
1907	167	per 1000
1908	174	per 1000
1909	177	per 1000
1910	155	per 1000
1911	163	per 1000

These figures seem to indicate that on the whole the dispensary system of prophylaxis is not a decided success. The gonorrhea rate shows a decrease in the last two years, but considering the amount of education and warning that has been given along with prophylaxis the reduction is certainly not very striking. It must also be remembered that in the last year a law was put in force

in the Army, similar to a law in the British Army, which deprives a man of pay during the time he is incapacitated from a venereal disease. This has been a powerful factor in restraining the men and making them take greater care in applying preventatives. The great increase in the syphilitic rate for 1911, the Surgeon General thinks is due to using the Wassermann test more frequently and admitting men to hospitals for treatment with salvarsan. Nevertheless the primary admission rate shows an increase also going from 3 per thousand to 4.

The Army also used tubes along with their dispensary and hospital systems, chiefly during the last two years. They are not considered as effective as the other methods by a majority of the medical officers, the trouble being that the men will not use them properly and cannot be checked later if infection has followed the use of a tube. These objections as far as they relate to the Navy I will discuss later.

The following are Naval statistics:

Gonorrhea—		
1906 (no prophyl.)	59	per 1000
1908	56	per 1000
1909	102	per 1000
1910	104	per 1000
1911	92	per 1000
Chancroid—		
1906	12	per 1000
1908	12	per 1000
1909	27	per 1000
1910	33	per 1000
1911	31	per 1000
Syphilis—		
1906	23	per 1000
1908	19	per 1000
1909	26	per 1000
1910	22	per 1000
1911	27	per 1000
Total—		
1906	87	per 1000
1908	88	per 1000
1909	155	per 1000
1910	160	per 1000
1911	150	per 1000

The venereal rate seems to be less in the Navy than in the Army probably because the opportunities for exposure are less. Gonorrhea showed a decrease for the first time last year. Chancroid seems to have remained about the same while syphilis has increased slightly up to date.

The opinion I stated last year * still holds good: "From these reports it seems fair to conclude that prophylaxis is possible but it takes a great deal of care and vigilance on part of the medical officer and the double method must be very rigorously applied in order to be effective. In civil life where strict routine and control of men are impossible it is impracticable."

Dunbar,† whose experience in the Bureau of Medicine and Surgery makes his opinion especially valuable, concludes as follows on the results of the double or dispensary system of prophylaxis: "That the incidence of gonorrheal rheumatism in 1911 indicates a higher rate than reported. That the reduction in the total rate to 150 in 1911 is inconclusive as to the efficacy of the method in use as equal or greater declines have occurred without it. That there is no reduction in the syphilitic rate. That the total damage from venereal disease in 1911 shows a slight reduction from that of the ten years, 1895 to 1905, but an increase over that for 1910. That the statistics fail to show any appreciable immunity from infection afforded by the use of drugs after a considerable time has elapsed since exposure to venereal contagium. It is well to recommend the application of antiseptics at the earliest possible opportunity after intercourse."

That seems to sum up the situation pretty well. Nor is it at all a wonder that it should be so. Had Metchnikoff merely made an announcement that calomel mixed with fat would prove antiluetic if used at convenience some indefinite time after contact, there could not have been more variance in composition and delay in application than there is at present. Few of the salves used in the Navy conform to the original formula and none of them are applied within an hour as is done in most of the laboratory experiments. Whether or not the effective time limit is one hour, or more than that, is hard to say in the absence of positive proof. Metchnikoff found that twenty hours afterwards calomel salve had no effect. The time limit for syphilis, however, is perhaps longer than that for gonorrhea. We have some direct evidence on this point from Wolbarst's case which I shall recount later. In those reports of the Army and Navy which describe individual instances the most marked diminution occurs usually in the syphilitic rate. But the best that can be said is that protection may or may not be afforded. Gonorrhea and chancroid are hardly preventable longer than a few hours after contact. The evidence is conclusive that very few infections can be aborted after eight hours have elapsed.

The next step in the progress of prophylaxis was made when the necessity for supplying an immediate preventative became apparent. Raymond had already tried to accomplish this, but his packet was too complicated. We have seen that some of the earlier experimenters incorporated other antiseptics with the mercurials. Maus, in the Army, combined thymol in 5 per cent. strength with Metchnikoff's salve and had some very encouraging results with it. He gave this formula up later and advocated the uncombined calomel salve as effective against all three venereal diseases. A series of experiments was made at the laboratory of the Army Medical School which proved the error of this supposition and demonstrated the value of a 3 per cent. phenol, 3 per cent. camphor, 25 per cent. lanolin and 44 per cent. lard ointment. The present Maus tube contains this formula.

Siebert tested the antiseptic value of 33 1-3 per cent. calomel salve with *Staphylococcus aureus* and found that it was very poor, being six to eighteen times as weak as corrosive sublimate under the same conditions in 4 per cent. strength. Henry, in the Navy, on the other hand found simple calomel ointment very efficacious in reducing the venereal rate on the U. S. S. Rainbow.

As a result of using fine, soft rubber catheters to irrigate the urethra with argyrol solution, in the double method of prophylaxis on board the U. S. S. *St. Louis*, in 1909; I tried later to place an ointment high up in the urethra for the same purpose by joining the tip of a catheter to a collapsible metal tube. The ointment used was Metchnikoff's, modified by the addition of 1 per cent tricresol. The latter was chosen as it seemed to be ideally suitable for the purpose. Post and Nicoll had proven that

*Medical Record, August 23, 1912.
†*Military Surgeon*, February, 1913.

it was the most potent of the phenol group. In 1 per cent. solution it is more powerful than phenol, chinosol, creolin, lysol, etc., killing not only the gonococcus but also the streptococcus, pneumococcus and bacillus of typhoid fever after a minute's exposure. Ducrey's bacillus of chancroid is considered no more resistant than these organisms; so, with its other qualities—freedom from disagreeable odor, color, irritation and ready miscibility—tricresol was given the choice over other antiseptics.

In this place I would also like to take time to pay tribute to Metchnikoff's genius. There is a tendency in this country to consider every variation of calomel salve as a brand-new discovery in the domain of venereal prophylaxis. Every man who adds a grain of carbolic acid to calomel salve thinks of it as his own particular system, forgetting that without Metchnikoff's work, not only in the proving of calomel salve, but also in establishing the communicability of syphilis to apes and thereby opening up the doors by which other experimenters in prophylaxis can arrive at definite, scientific ends, he would be no closer to the problem's solution than our friends whom I have mentioned in the first part of this paper. Nothing that any one has done could have been done without Metchnikoff's work and to him and him alone is all the honor due that may follow in the wake of the movement.

Tube prophylaxis is the only system that can ever give any marked beneficial results because it is the only one that provides for immediate application without which no success can be expected. Even the firmest believers in the dispensary method acknowledge that immediate application is the ideal way and object to it only on the grounds that enlisted men will not use it. In civil life this objection is at once removed. Here we are dealing most of the time with an individual who desires to be protected and only needs to be told what to do. In the services, my experience has taught me that sailors will use tubes providing that the advantages of tube prophylaxis are pointed out to them by such educational methods as personal instruction, photographs of failures by other means, explanations of the reason why medicaments must be applied early, etc.

Again it is urged that most exposures are made under the influence of liquor when the man is incapacitated from using the tube himself. Again, from my inquiries on the U. S. S. *Delaware,* I am of a different opinion. Many times this is the case of course and it would be better if all houses of prostitution and all private prostitutes were required by law to protect those with whom they have dealings. In some places a law has been proposed making houses of this sort legally liable for damages if a disease is caught there. I think this an excellent law, and it should be made to apply to individual prostitutes also. A regulation like that would not only do away practically with the entire evil of venereal infection but it would make it almost impossible for any form of prostitution to continue.

One objection that I would make to tube prophylaxis myself is that a number of tubes have seen the light of day which apparently make no effort to embody what is known to be necessary to provide protection. Thus one tube which I examined appeared to be nothing more than white vaseline; it bore the name of a Pittsburgh firm and purported to be used in the Navy. Other tubes have sprung up without any scientific reason for their existence and somehow they all claim to be used in the Navy. As a matter of fact the only tube to receive any official recognition in the Navy is the one I devised. The Maus and possibly one other tube have been used in the Army.

As the efficiency of calomel has been pretty well proven experimentally when applied soon after contact it remains to be inquired into if this salve can be so modified as to be effective against gonorrhea at the same time. In the laboratory Russell and Nichols tried the experiments mentioned above. Their procedure consisted of injecting the ointment to be tested into the urethras of men suffering from acute gonorrhea after the discharges had been diagnosed positive by stained smears and growths upon ascites agar. After injection, the ointment was allowed to remain in the urethra about fifteen minutes, then the mucous membrane was washed clean by urination and a drop of the residue expressed into the meatus. This drop was streaked over ascites agar, incubated, and suspicious looking colonies examined with Gram's stain. Their first experiments were with the tube used in the Army, containing: Calomel, 25; phenol, 3; camphor, 3; lanoline, 25; lard q. s., 100. It proved effective in seven out of eight instances. Next they tried a 30 per cent calomel in lanoline ointment, a 3 per cent phenol in lanoline ointment and some more of the Army tubes, the latter being designated as the *new Army* tube. These various ointments proved to be failures in eight out of eight cases.

I tried to repeat their work with Army tubes bought in the open market.* I could not find out if they were the old or the new Army tubes, but a leaflet referred to the experiments of Russell and Nichols so I concluded that they were made after the old Army formula which was found to be the most efficient. The results obtained were at a complete variance from theirs, however, all six cases yielding positive growths after injection of the ointment. The Navy tubes were tried in sixteen cases. The technique was changed a little, using a platinum loop scraping instead of expressing a drop of the urethral residue into the meatus. The sterilization was done at noon and the men saved their morning urine in order to be sure that the urethra should be well washed out. It was desired that the general germicidal power of the ointment should be tested, so all colonies, not only gonococcus, were noted and considered as failures for the tubes. Nine out of sixteen tubes prevented all growths.

Then another series was made, milking a drop of fluid into the meatus after urination, as in the Army experiments. At first glance it appears that using the platinum loop would obtain material perhaps deeper from the folds of the urethra, etc., but when you consider that all the contents of the glands of Littre and the lacunæ contribute towards the drop of fluid that presents at the meatus when the penis is milked, this becomes doubtful. Out of this second series of sixteen cases seven gave no growths. In all the tubes, however, the growths were much less than in the tubes which were streaked before the ointment was injected. Since these experiments the strength of tricresol in the ointment has been raised to 2 per cent to procure a wider margin of safety. These results are very interesting, but it must be borne in mind that rendering an acutely infected, purulent, gonorrheal urethra sterile, and

**Journal of Am. Med. Association,* May 24, 1913.

preventing the growth of gonococci in a normal urethra, are two widely separated tasks and the results from the former must be judged only relatively in considering their value in the latter.

I know of no other laboratory work of this kind and the statistics from the practical application of the tube system are meager. The tubes in the army are used in conjunction with the dispensary and hospital systems and I have seen no records of their own, apart from the general venereal tables of the army. Recently a circular letter was sent to the medical officers of various battleships requesting whether any venereal diseases had followed the use of such navy tubes as they were able to account for. This yielded a record of 431 tubes without an infection. This together with a series of 492 on my own ship makes a total of 923 tubes used without an infection of any kind.

But after all the most interesting comparisons in venereal prophylaxis to observe are those unfortunately rare cases where, intentionally or unintentionally, the deadly parallel has been obtained. Some of these have already been published, but widely apart, and some have but recently come under my own notice. Those pertaining to syphilis I will give first.

In 1908 Wolbarst reported the following case. t appears that A. and a friend B. had spent the ight with a woman who, by her own admission, as suffering from active syphilis. Both men had opulated with the woman several times during ne night and the chances for infection were as good as they could possibly be. Early in the morning about six hours after his exposure A. came to Wolbarst, stated his predicament, and demanded that something be done for him as he expected to be married shortly. Wolbarst applied a 30 per cent. calomel ointment for five minutes over those places that seemed likely to be infected and gave him some of the ointment with instructions that it should be applied every four hours until used up. In the meantime B. had hurried away on a train for the West. The woman was examined and found to have opposing surfaces of the labia majora covered with papules, some as large as a cent, condylomata about the anus, and ulcerations in the mouth. Four months later A. was still free from any luetic manifestations while B. returned a month later with a hard chancre on the coronal sulcus and three weeks after that developed an unmistakable papular eruption.

At Michigan City, Blech reported the case of a sergeant who exposed himself to a woman having a chancre on the right labium. He was protected within an hour by calomel salve and escaped infection. Bonnet reports the case of three friends who had intercourse on the same day with a syphilitic woman. Two of them used gray salve and remained free from infection, being examined two months later. The other one after three weeks developed a chancre. Bonnet also reports a case of a French soldier who transmitted syphilis to his enamorata. Later, at the time of her secondaries, he wished to rid himself of her and managed to transfer his charge to a friend. This man had repeated intercourse with her and at about the time her manifestations were leaving her, the girl had relations with still two other men. All of these last three men used the regular calomel salve and had not developed lues at the time of an examination three months later.

As an example of the protection afforded in gonorrhea it is necessary to quote the series of exposures made in Newport in 1912. A fracture case in the Naval Hospital was given leave to go to the city and reported gonorrheal infection a few days later. The woman, an inmate of a brothel, was easily identified and slides taken from her vagina, cervix, and urethra all proved positive. Ten exposures to this woman were obtained, all using navy tubes as a protection. One of the ten returned and exposed himself several times afterward without this precaution. The nine protected contacts escaped while the one who went back was infected, making two, with the fracture case, who were unprotected.

Hospital Steward B. in the navy, who had assisted me in devising the navy tube, exposed himself on July 4. On July 7 another man cohabited with the same woman. The hospital steward used a tube within an hour after contact while the other man remained unprotected and was infected. The former did not develop any disease. This same steward had knowledge of three men who were all infected by the same woman, one of the men after he had taken the regular ship's prophylaxis. In order to prove his confidence in the tube he exposed himself, used the tube a half hour afterward and escaped infection. On the U. S. S. *Delaware,* three men had all night contacts with the same woman. Two of them used tubes between eight and nine hours later; the other did not protect himself at all. The three of them were infected. Still another had two contacts with this same woman in the space of an hour, employed a tube immediately after the last, and did not suffer any infection.

This last case is a good illustration of what I have constantly insisted upon, namely, that no prevention, whether in tubes or in the dispensary, is of sufficient value to make it worth while unless used immediately. I am glad to be able to say that the tendency in the navy is toward that opinion. The army is still inclined perhaps the other way. But I feel certain that as soon as some one will give the tubes a thorough trial to the exclusion of other methods, their superiority will be established beyond all doubt.

ANTITYPHOID VACCINATION.

By ALVAH H. DOTY, M.D.,

NEW YORK.

WITHIN recent years the medical profession has been called upon to decide as to the value of various sera and vaccines prepared for the prevention and treatment of disease. While many of these have been found to be practically worthless others have been approved and are now in common use. As the laboratory supply of these agents is increasing it is not only proper but necessary that we should stop to consider to what extent their employment is justifiable.

Those who have had personal experience with this form of treatment and have carefully and disinterestedly studied the defects as well as the good it may accomplish are cognizant of the fact that it is the abuse rather than the use of a vaccine or serum which must be carefully guarded against, for the enthusiasm of the discoverer is naturally very infectious, and those who have no time or inclination to investigate the possible shortcomings of these

agents or how far they may be practically applied are quite apt to accept them with but little limitation. We know this takes place with every valuable and well-proven medicinal agent, for they are often improperly and too extensively prescribed. This condition is far more apt to occur in connection with a vaccine or serum, for the hope they extend is very great, as they usually apply to diseases which contribute largely to the general mortality; under these conditions the most extended consideration is given any means which offers protection to the public health.

My intention is not to minimize the value of this form of treatment within reasonable limits and in the hands of those who are equipped to administer it, but rather to inquire into its range of usefulness and to suggest that we carefully consider its defects as well as the protection it extends.

At the present time it is probable that the antityphoid vaccine is uppermost in the mind of the profession and through the publication of popular articles the public is more or less familiar with the literature of this subject. The statistics furnished by the Medical Department of the United States Army regarding the preventive effect of the antityphoid vaccine among the officers and men of this branch of the public service have been chiefly responsible for the very favorable reports relating to the subject. How far investigators at home or abroad may disagree with these conclusions is not the purpose of this article, beyond the statement that there are dissenters who question somewhat the value of the antityphoid vaccine and who also believe that under certain conditions it is not without very unfavorable constitutional effects. However, it must be said that nowhere has a more careful and exhaustive study been made of it than by the medical officers above referred to.

It has been stated that the antityphoid vaccine as a preventive measure is likely to be used as generally as the vaccine employed in the prevention of smallpox; this will hardly occur, for typhoid fever is caused by infection taken through the mouth and with proper care in the selection of food and drink and cleanliness the danger from this source may be largely averted. No such protection is available in smallpox, for this disease is contracted by personal contact and we may become infected through sources over which we have but little control, largely in the form of mild or unrecognized cases. Under these conditions we are justified in resorting to special means of protection which otherwise might not be called for. Antityphoid vaccination is a more formidable operation than vaccination against smallpox and it is more necessary that the one treated should be kept under careful observation: besides it must be more often repeated to secure the immunity which it confers. The frequency of this would alone involve serious opposition on the part of the public. One or two *successful* revaccinations in smallpox are believed, and very properly so, to confer all the immunity which may be secured in this direction; very frequently the immunity conferred by the primary vaccination lasts a lifetime. It is the custom, however, as a precautionary measure to be vaccinated every eight or ten years; even during the presence of smallpox this is secured with considerable difficulty on the part of the health authorities.

The use of antityphoid vaccine among soldiers and sailors presents a very different feature in connection with this treatment. The protection of these men against infectious disease is a responsibility which very properly rests with the medical officer in charge; furthermore, soldiers and sailors are employed for the protection of the public and must be prepared at any moment to deal with emergencies. In connection with this duty they are frequently transferred from one place to another and may often be exposed to sanitary conditions which are very bad, therefore unusual or more extended means of safeguarding their health is justifiable.

There are other emergencies in connection with outbreaks or anticipated outbreaks of typhoid fever and also other conditions where the vaccine may be useful. It has recently been employed as a preventive measure in hospitals. It would seem that if the typhoid stools and the receptacles which held them are at the same time disinfected with boiling water or steam as they should be, for there is no other safe or practical way of dealing with them, and if strict cleanliness on the part of the nurses and attendants and elsewhere is strictly enforced, there is no reason why secondary cases should occur except in some special instances which would not call for any change in the hospital regulations dealing with this disease. If antityphoid vaccine is used in these institutions great care must be taken lest it favors carelessness among nurses and other employees, for if it is depended upon I am quite sure that in some way relaxation will take place in the enforcement of the sanitary measures which are imperative in the care of typhoid fever.

During the past year the public in various parts of the country have been officially advised to secure the benefits of the antityphoid vaccine, particularly those who are going abroad or away from home. I do not believe a general recommendation of this kind is proper or wise, nor do I accept the statement that this means of prevention involves no risk, particularly to those who might present themselves for treatment if this agent were generally and indiscriminately employed, for it is generally conceded that any acute infectious or organic disease or impaired health contraindicates the use of this agent. I believe those in charge of the public health should deal in the most cautious and conservative way in approving or recommending a serum or vaccine for general use. Aside from the unpleasant results which may follow its employment in this direction it would extend a license or even a stimulus for the production of various agents of this kind, many of which would be not only worthless but would be in the hands of improper persons and would at least divert the public mind from the use of proper and effective preventive measures which in order to be successful must have the public's co-operation.

There are probably not many practical sanitarians who believe that the use of this vaccine will have any considerable effect in limiting the extension of typhoid fever throughout the world, except in the special condition already referred to, for the portion of the population which is most apt to transmit this disease will not generally accept this form of treatment. It has been particularly suggested that persons going abroad are appropriate subjects for this treatment in order that they may be relieved from any anxiety as to the danger of contracting typhoid fever while away. I know of no statistics of scientific value which have been presented and I am quite sure there is nothing in my own experience to indicate that those who travel under modern conditions and who know the value

of proper sanitary measures with which all should be familiar are any more prone to contract diseases while away than when they remain at home. Besides, it is quite probable that the carelessness in the way of sanitary precautions which would be likely to follow antityphoid vaccination might lead to risk which would not otherwise be assumed.

The prevention or elimination of certain diseases by the co-operation of the public in carrying out what may be called natural preventive measures is the hope of the practical sanitarian, for he knows that nothing but success can follow this course. During the past ten years rapid strides have been made in this direction chiefly through the education of the public in matters relating to general sanitation. The public is now familiar with the importance of cleanliness, pure food and drink, personal hygiene, and the inestimable value of maintaining our resisting power as a protection against disease. Among other things the public has been taught that typhoid fever, probably more than any other disease except cholera, may be prevented by complying with modern sanitary laws, and it is fast becoming impressed with this means of protection and insists upon being surrounded by proper sanitary conditions to an extent never before known. Proprietors of summer hotels are being called upon to furnish information regarding the sanitary condition of their buildings and from what source their milk and water supplies are obtained, and the diseases which are prevalent in their vicinity. These men now find that it is of commercial value for them to pay careful attention to these conditions. Country boarding-houses, which are almost always insanitary, are being much less patronized because the public has been cautioned against these places. In the city this interest in sanitary matters is also apparent in selèction of apartments, etc. Employers have become very active in the welfare of their employees and their protection against infectious diseases, particularly tuberculosis and typhoid fever, through modern sanitary measures. Never before has a point been reached where the sanitarian and the public have so effectively worked hand in hand in the preservation of the public health, and if this course is maintained there is but little doubt what the result will be so far as the elimination or diminution of certain forms of disease or the progress made in raising the standard of health in the individual is concerned, for it is the logical and proper means of securing this end.

I believe those who will give this subject careful consideration will be convinced that the employment of the antityphoid vaccine as a preventive measure should be strictly confined to conditions or emergencies where it is deemed justifiable to carry out special means of protection. Under these circumstances unpleasant results may be avoided and the public mind is not disturbed or its faith weakened in modern sanitary methods in which its cooperation is so urgently needed and which are so essential to the preservation of health.

62 West Fifty-eighth Street.

Effects of Ablation of the Parotid.—Lorenzo Neri in a preliminary communication presents the result of his experiments on the physiological and pathological effects of ablation of one or both parotids. He finds that removal of one parotid results in connective tissue hyperplasia of the remaining gland with a corresponding atrophy of its glandular parenchyma. Ablation of one or both glands causes hypertrophy of the thyroid.—*Giornale Internaziole delle Scienze Mediche.*

EXTRACT OF THE PITUITARY BODY OF THE OX IN THE TREATMENT OF RHEUMATIC ARTHRITIS.

A PRELIMINARY REPORT.

By CHARLTON WALLACE, M.D.,

NEW YORK,

ORTHOPEDIC SURGEON, ST. CHARLES HOSPITAL FOR CRIPPLED CHILDREN,

AND

FRANK S. CHILD, M.D.,

PORT JEFFERSON, N. Y.

RESIDENT PHYSICIAN, ST. CHARLES HOSPITAL FOR CRIPPLED CHILDREN.

During the past few months several kinds of joint rheumatism have been treated with pituitary extract at St. Charles Hospital, Port Jefferson, Long Island. The improvement in the patients is noteworthy. In consideration of such a short period of treatment and observation nothing more than a preliminary report can be made. No dissertation upon the etiology or classification of articular rheumatism is attempted here. The patient's disability is briefly described. In addition to receiving injections of pituitary extract all of the St. Charles Hospital cases have lived day and night in the open air, have had the regular hospital diet, and the same bathing and care as the other children.

Case I.—A girl three years of age was admitted to St. Charles Hospital November 25, 1912, H. No. 122. The family history is of no particular interest. She was a nursing baby and always in good health except for persistent enuresis and one attack of dysentery about nine months preceding the involvement of the first joint. When nineteen months old the mother noticed stiffness and evidence of pain in the left ankle and right knee. One month later the neck became stiff and painful. Both hips were next affected and in the summer of 1912 both shoulders, elbows, wrists, and all the fingers. The patient has had frequent exacerbations of severe pain and swelling around the joints.

Examination upon admission showed her to be in very poor general condition, weighing 27 pounds. She was brought to St. Charles in arms because of crying on any attempt at walking. The motions of all the joints of the extremities and the cervical spine were greatly restricted on account of pain. The interphalangeal joints of both hands were swollen, especially the thumbs. There was no fluctuation. The joints of the extremities were slightly flexed; the thighs were adducted. The muscular atrophy around the joints was noticeable. The lower regions of the spine seemed not to be affected. The larynx was slightly congested. The urine was normal, except for a slight increase of indican. The blood-pressure was 100. The blood examination demonstrated nothing of special interest. The *x*-ray showed coxa valga of both femora, but nothing abnormal in the other bones and joints.

Diagnosis.—Multiple arthritis (resembling Still's disease).

Treatment.—Under thoroughly aseptic precautions intramuscular injections of 1 c.c. of pituitrin were begun on December 3, 1912. At this time the patient was constipated and enuresis was present. On December 12 the dose was increased from 1 c.c. to 2 c.c. daily. On December 14 the patient had diarrhea and the laxative was stopped, and then beginning on the 20th the pituitrin was omitted for a week and the laxative resumed. At this time the patient was complaining of not feeling well and on the 25th, five days after stopping the pituitrin, she vomited, although the nausea had begun before this, and the indications seemed to be that the gastric symptoms were caused by the pituitrin. On December 26 the swelling in the fingers had diminished, the pain had lessened, and the general appearance was improved. On December 28, pituitrin in 2 c.c. doses was given every other day, and on January 22 it was stopped because the swelling of the thumbs and all pain had disappeared. February 14 there seemed to be a slight swelling of the thumbs and 2 c.c. of pituitrin was given on each of two days, and following this the dried gland was administered in doses of nine grains a day. The powder was continued until February 26, 1913, when it was noted that the swelling had increased; then 3 c.c.

of pituitrin was given intramuscularly in addition to the dried gland. Both were continued until March 6 when the patient began to vomit and the injections were discontinued, but the dried gland was administered until March 14. At this last date all swelling and pain had disappeared and the patient seemed cured. Altogether she had 80 c.c. of pituitrin and 231 grains of dried pituitary gland of the ox. Since taking the treatment the patient's bowels have been in normal condition, it rarely being necessary for her to take a cathartic. The enuresis has continued, but not so frequently as when the pituitrin was given.

The effect on the blood.—The leucocytes were decreased during treatment and increased when it was withdrawn. The percentage of the hemoglobin remained normal throughout. The large mononuclears increased during the treatment and diminished when it was stopped. The small mononuclears showed a tendency to decrease during the administration of pituitrin but this was not continuous; several months after it was stopped they increased. The polynuclears seemed to be permanently affected as they diminished with the pituitrin and remained so. There was a notable increase in the eosinophiles with the giving of pituitrin and they decreased on its withdrawal. The basophiles and transitionals were present during the treatment and absent afterwards.

This patient's general condition was improved and she gained three pounds in weight. She was relieved entirely of all pain at the end of thirty-one days and has remained free from it since. All swellings have disappeared and the functions of the joints are normal, except the hips, where abduction is limited due to muscular contraction.

Several doses started diarrhea which soon subsided; the bowels have become regular. There seemed to be an increased amount of urine during treatment. For the first few doses the indican and urea showed an increase but these soon were diminished to normal. The heart's muscle tone was improved and the blood-pressure raised to 120 mm. The only ill effects of the pituitrin were the nausea and vomiting, due probably to a cumulative action of the large doses.

This was our study case and the response to treatment was not as early as in the other cases we have treated. But this patient's disease seems to be arrested and she enjoys playing with the other children. She appears perfectly well except for a peculiar hip limp due to the coxa valga and the muscular contractions.

Case II.—The second patient, a boy, 12½ years of age, was admitted to St. Charles on May 1, 1913. H. No. 163. His family history was negative. The onset of his complaint occurred two years ago, when he had pains in his legs, soon becoming localized in the ankles and knees, which were swollen. One month later his neck and jaws were similarly affected. Previous to his admission, on account of the condition of the ankles he had not worn shoes for several weeks and he had been confined to a chair for one month. With great pain and difficulty he was able to walk about 100 feet. When examined on the above date the patient's general condition was poor and his weight was 60¼ pounds. His neck was almost rigid and very slight movements caused pain. He could separate his teeth only a finger's breadth. His ankles and knees were swollen and painful, also the metacarpophalangeal joint of each index finger. The hips, shoulders, elbows, and wrists were unaffected as well as dorsal and lumbar region of the spine. A systolic murmur could be heard in the third left intercostal space. The blood-pressure was 105 and the temperature 98.6° F. The urine was normal except for the presence of indican. The blood examination indicated nothing of interest.

Diagnosis.—Multiple arthritis.

On account of the volume of pituitrin required for intramuscular injection and the disagreeable gastric effects, we experimented and found that an extract could be made from the desiccated pituitary body of the ox, which is stronger and would serve our purpose. We could use one-third the quantity and secure a better physiological response; and at the same time a fresh preparation, which was well borne.

This patient was kept in bed for one week on account of his severe pains. He received 1 c.c. of the fresh fluid extract daily for one week, when he was encouraged to get out of bed and move around. One cubic centimeter was given to him every alternate day for two months, when the pain and swelling disappeared. At the beginning of the third month it was given every fourth day; but during this month the pain and swelling began to reappear in the same joints affected upon admission. He then received 1 c.c. of fluid extract daily for one week and every alternate day to the end of the third month, when he was discharged August 1, 1913, with the disease arrested. The treatment covered three months during which time fifty intramuscular injections of 1 c.c. of the fluid extract of pituitary were given; eight of 0.5 c.c. were tried but had to be abandoned. The total amount administered to this patient was 54 c.c.

A laxative was given to him at bedtime for one month, when the bowels became regular. Elixir of glycerophosphates and extract of red bone-marrow were given to him as a tonic. During the first two weeks of treatment his temperature showed an irregular elevation ranging as high as 101° F., but averaging 99.6° F.; after this the temperature was constantly normal.

Upon discharge the patient had gained 7¼ pounds and his general condition had been markedly improved. All pain had disappeared and the motions of all the joints were normal, except the upper cervical and temporomaxillary articulations. In all probability these joints were stiff on account of the muscular contractions. But he could walk two miles without fatigue or discomfort and he could roller-skate and row a boat well. The constipation was relieved; the bowels were in a normal condition. He had no nausea or other disagreeable symptoms; there was no increase in the amount of urine excreted. The heart murmur was still present, although the muscle sounds were improved. The blood-pressure remained elevated to 160 mm. Examination of the blood showed practically no change.

Case III.—A girl 9½ years of age was admitted to St. Charles Hospital, June 24, 1913, H. No. 160. Her family history is of no interest but the patient has had bronchitis and measles. Four years ago she had a painful and swollen left ankle, followed three weeks later by a like condition in the right ankle; gradually all joints became affected. Upon admission she was bed-ridden, had pains in the hips and knees, and disability of all the joints. Any attempt at active movement caused pain. She was emaciated, weighing 30 pounds.

When she was examined she was lying supine with all joints flexed. She was unable to change her position and any attempt at passive movement caused severe pains. The spine was held in flexion, as well as the joints of the extremities. The latter appeared enlarged and there was marked muscular atrophy about them. The right knee was subluxed. There was chronic congestion of the lungs and the liver extended 4½ inches below the costal margin in the right mammary line, and to the left of the midline as far as the left mammary line. The spleen was palpable. The abdomen was distended and the circumference at the umbilicus was 20 inches. The heart sounds were fair, the blood pressure was 90 mm., and there was 1 gm. of albumin per liter in the urine. She had a peculiar papular rash on the skin and some ulcers on the extremities. She also had external hemorrhoids and pruritus valvæ.

Diagnosis.—Multiple arthritis (Still's disease).

This patient has had 1 c.c. of fluid extract of pituitary per day for ten days, and 1 c.c. on alternating days for 18 doses, making 28 injections all told. She is still under treatment. At present the pains have been relieved and the motions in all the joints are improved. The patient can sit up and her general condition is better, although she has lost half a pound. The liver has receded 1¼ inches and the circumference of the abdomen has diminished 1¼ inches. The skin eruptions have healed somewhat and the lung congestion has greatly lessened. There is only ¼ gm. of albumin per liter in the urine and the pruritus vulvæ is cured.

The prognosis in this case has changed from fatal to favorable:

Case IV.—This patient is a boy 8½ years of age and was admitted to St. Charles Hospital on June 14, 1913, H. No. 187. The family history is negative except that a

brother became blind at the age of ten and died in six months. He has had measles and has had pneumonia twice. He has always had a poor appetite. Frequently he has complained of headaches. He had a desire to climb to heights in order to jump off, and many times he has bruised himself doing this. His pains began two years ago in both shoulders but there was no swelling. Two weeks later he had pains in both knees and they became enlarged. He walked to the hospital with plaster-of-paris bandages about both knees. The pains in the knees had been severe and constant when these bandages were not worn.

Upon examination it was found that his general condition was poor, weight 59¼ pounds; both knees were swollen and painful. No other joints were involved. No heat or fluctuation. The swellings in the knees felt doughy. The motions were limited chiefly on account of the pain. The right knee could not be extended fully, but could be flexed to a right angle; the left knee could be extended fully but it could not be flexed beyond a right angle. Any voluntary motion in these joints was slow and painful. In other respects his physical condition was normal; the blood-pressure was 115 mm.

Diagnosis.—Arthritis of the knees.

The treatment consisted in omitting all dressings and in giving the fluid extract of the pituitary intramuscularly. An injection of 1 c.c. daily was given seven times and then on alternating days 16 times.

His general condition has markedly improved and he has gained 1½ pounds. He is able to run and jump without pain. The swellings have disappeared and the knees look normal. There is no pain except on extreme flexion. The urine and the blood are normal. The blood-pressure is 170 mm.

Case V.—On June 30, 1913, a girl 6 years old was admitted to St. Charles Hospital, H. No. 162. The family history is negative except that her father was alcoholic. She was a nursing baby until seven months of age. Then she was fed modified milk. She was backward in her general development and did not walk until 18 months old. She has always looked pale and sickly and is said to have had heart trouble. She had measles and diphtheria. In January, 1912, the mother noticed that both ankles were swollen and painful. This lasted for a few weeks. In November of the same year there was a return of the pain and swelling in the ankles, and pains began in both sides of the neck. Gradually other joints became affected and finally all the joints were painful, except those of the hands, the jaws, and the shoulders. The back was stiff. The pains were increased by any attempt to bend the spine. In the spring of 1913 she complained of pains all over the body.

Upon examination June 30, 1913, her general appearance was poor, weighing 34 pounds. She was able to walk but the gait was careful and the entire vertebral column was stiff and held in a rounded attitude. Attempts to move the spinal joints caused pain, especially in the dorsolumbar region. The neck was very rigid. Both hips were in slight flexion and adduction, the adductors being contracted. No swelling was noticed. The teeth were in poor condition. A loud systolic murmur, heard over the apex of the heart, was transmitted to the left. Her urine was normal and the blood-pressure was 110 mm.

Diagnosis.—Multiple arthritis.

On August 14, 1913, the urine was still normal and the blood-pressure was 120 mm. This patient has had 25 injections of 1 c.c. daily, and these were followed by 7 of 1 c.c. given on alternating days. Her general condition has improved and she has gained 1¼ pounds. She plays and romps with the other children. The neck and hips have a normal range of motion but the motions are limited in the dorsolumbar region. She is doing well and is still under treatment.

Case VI.—This patient is a girl fourteen years of age and was admitted to St. Charles Hospital on July 15, 1913, H. No. 196. Her family history could not be obtained. She had erysipelas when ten years old, and has had frequent attacks of tonsillitis. One year ago she had pain in the back and neck and pain in the ankles, knees, hips and shoulders. Motion in all of the affected joints was restricted, especially in those of the back and neck. Four months ago the joints of the hands became affected and the hand could not be closed. These joints one month later became painful and swollen. Upon admission her general condition was poor; weight 65½ pounds. She walked with the smallest possible motion in the hips and knees. Rotation in the cervical region caused pain. The lateral movements of the other regions of the spine were much diminished and painful. The temporomaxillary joints were affected and swollen, the mouth not opening to its normal width. Any attempt to move the ankles, knees, hips, wrists, and shoulders to their full range caused severe pain. The fourth and fifth fingers of both hands were held in flexion, yet there was inability to flex completely all of the fingers. The digits tapered; the wrists were enlarged and fluctuation could be produced on their dorsal aspect. The right parotid gland was swollen. The abdominal and thoracic organs were normal. The urine and blood were normal. The blood-pressure was 100 mm. The tonsils were enlarged. The *x*-ray showed cloudiness on the spine of the tibia.

Diagnosis.—Multiple arthritis.

Twenty-five injections each of 1 c.c. of the fluid extract of the pituitary body were given by August 14. The patient's general condition has improved and her weight has increased 1¾ pounds. The pains in all the joints and the swellings have diminished. All motions have improved except those of the fifth and fourth fingers. The enlarged parotid gland has considerably lessened in size. The tonsils remained as they were upon first examination. There was no change in the urine or *x*-ray findings. The blood-pressure was raised to 135 mm.

The following five adult cases were from private practice and only brief outlines will be made of them:

Case VII.—A woman 63 years old had had pains in the neck, right elbow, knees, and hands for five years, accompanied with considerable disability. Upon examination on May 19, 1913, it was found that the cervical region, right elbow, knees, and all of the fingers were affected. The distal phalanges of the fingers were enlarged. *X*-ray showed exostoses at the interphalangeal joints.

Diagnosis.—Osteoarthritis.

This patient was treated until July 8, 1913, and had 19 injections of 1 c.c. of the fluid extract of the pituitary, given on alternating days. On this date the pains and stiffness in the neck and elbow had disappeared, but some tenderness remained in the fingers. All of the finger joints showed improvement. This patient received great relief but discontinued treatment of her own volition.

Case VIII.—Man 25 years old has had muscular pains in the back for more than one year. During that time he was unable to rise from the supine position without assistance from his arms. No joint involvement. He was examined on June 8, 1913. The back muscles were tender; no nodular formation was felt.

Diagnosis.—Muscular rheumatism.

The patient had six injections from June 30 to July 19, and he has had no further pain.

Case IX.—This patient is a woman 30 years of age, and for nine months has had pain and disability in the right shoulder. An examination was made on July 6, 1913, and there was pain in the right shoulder joint when extreme motions were attempted. No swelling was seen. She was unable to place her right hand to the back of her head. There was some grating felt within the joint and tenderness behind the articulation.

Diagnosis.—Monarticular rheumatism.

One injection of 1 c.c. of the fluid extract of the pituitary body was given on July 6, and another on July 7. After the second dose the motion was unrestricted and the pain had disappeared. The treatment was discontinued.

Case X.—This patient, a woman, 61 years of age, was seen on July 10, 1913. She gave a history of having been well until six months ago, when she began to have pain in her back and shoulders, and had severe pains down her right thigh along the sciatic nerve. Her suffering has been so intense that an opiate had been given every night for one month. At the time of examination, all motions of the back, especially in the dorsolumbar region, were restricted. Percussion on the spines of the lumbar vertebræ caused no pain; but the patient said that this would have been unbearable upon the previous day. There was no tenderness along the sciatic nerve, and flexion of the thighs with the legs extended caused no discomfort. The patellar reflexes were normal. The distal interphalangeal joints of the index and middle fingers of both hands were enlarged. The *x*-ray examination showed a peculiar exostosis on the lateral side of the body of the fourth lumbar vertebra.

Diagnosis.—Osteoarthritis.

On beginning treatment all opiates were omitted. Aspirin and pyramidon were administered until pituitary solution could be secured. From July 18 to 28 1 c.c. of the fluid extract of the pituitary was given daily; since then it has been administered every alternate day. She has worn

an ordinary tight-fitting corset throughout the course of treatment. The blood-pressure was elevated but she has had no disagreeable symptoms. Since her first injection she has had only one day of acute pain and her nights have been peaceful.

All of these cases showed improvement in the general condition; in the pains, swellings, and the motions of the joints affected, and in the effect on the bowels. The blood-pressure was elevated throughout the treatment, and had a tendency to remain so. There was a slight, irregular rise in temperature during the first week or ten days. Nothing significant was found in the blood and urine.

The adult patients were slightly nauseated and suffered head symptoms, such as giddiness, lightness, and headache.

The material used is made by putting 0.3 gram of the desiccated fresh pituitary body of the ox into 30 c.c. of sterile physiological salt solution. To this is added 0.3 gram of chloretone crystals, and it is allowed to stand for three hours. The mixture is then filtered through filter paper. The filtrate is boiled and kept in a sterilized bottle with a rubber cap on it. There is a tendency for this extract to deteriorate and it should not be used after it has been made three weeks.

Under thoroughly aseptic precautions the patients have had no sign of needle infection nor have they had much pain from the intramuscular injections.

One c.c. of the above preparation has been used in every case except the first one.

507 Madison Avenue.

THE COLON: ITS MALIGNANCIES.*

By JOHN F. ERDMANN, M.D.,

NEW YORK.

During the year 1910 I published two papers in reference to Tumors of the Colon. The first published in the *New York Medical Journal*, January 29, 1910, with the title, "Malignant Growths of the Sigmoid and Rectum." The second, published in the *American Journal of Surgery*, September, 1910, with the title, "Surgery of the Large Intestine."

In these two papers I reported a series of tumors of all classes, benign and malignant, numbering 45. Since publishing the above papers I have operated upon 40 additional patients for malignancy of some portion of the colon: Two being sarcoma of the perirectal region and easily removed by the posterior incision, *i.e.*, perineal in one instance, and retroperitoneal, *i.e.*, transperitoneal in the other. The remaining 38 patients were involved in the following regions of the colon: Cecum, 3; sigmoid, 11; rectosigmoid, 13; rectum, 8; transverse colon, 3. In addition to the above I have four patients under observation, who are too far advanced for operation, and who have, with proper care, little or no evidence of obstruction, and manage to exist fairly well under mild anodyne treatment.

In the classification used above, by the sigmoid I mean the freely movable sigmoid, while in the rectosigmoid I mean those in which the tumor involves the upper rectum and terminal portion of the sigmoid, better clinically classified by the area immediately behind the rectovesical pouch in the male.

Under the rectal distribution all growths from the anus to the above area are included.

Furthermore, in considering the sigmoid in this paper, the later-day anatomical classification obtains, that is, the sigmoid extends down to the third sacral vertebra, or, in other words, includes that portion of the gut formerly known as the upper or intraperitoneal rectum.

It will be seen that 21 out of the 3 operative cases and four additional ones not operated upon involved the rectum and rectosigmoid, while but 11 involved the freely movable sigmoid. Three each were in the cecum and transverse colon.

The youngest patient in this series was 26; tumor involving the sigmoid, and invading the left broad ligament and ovary; with this condition there was a history of a pronounced specific infection.

Two were patients with adenocarcinoma and evidences of diverticulitis, in all probability a previous diverticulitis developing into carcinoma.

In each case, when seen by me, the condition was well advanced and diagnosis easy, except one, a woman, whom I saw with a large pelvic tumor, which upon operation proved to be a malignant papilloma of the left ovary about the size of a seventh month pregnancy, and upon removal of the growth, discovered a tumor of her sigmoid. Excision of the tumor, with section, proved it clinically to be an adenocarcinoma, implanted on a complicating, or, rather, a previously existing diverticulitis. Microscopic reports by Dr. Ewing upheld the clinical diagnosis.

To what must we ascribe our inability to detect these growths at an earlier period? Modesty on the part of some patients in revealing their ills of this region is a great factor. Refusals to allow examinations of the anal and genital organs, also on account of modesty. Our too readily eased conscience in not examining such patients and accepting their diagnosis or that of their family doctors, as to piles, fissures, etc.

Slurring the importance of a detailed and minute history by incomplete examination of the rectal region. Fastidiousness, in many instances, is a profound factor; the absence of a glove or cot for the examining finger is an argument of defense by many a practitioner for not having examined the rectum.

Reserve in giving a complete history on the part of the patient, who fears a diagnosis of cancer and prefers to mislead the physician, rather than suffer the mental anguish of such a diagnosis.

Diagnosis.—In the early onset the symptomatology is sparse, and so vague and indefinite that a diagnosis is rare and difficult. The earliest symptoms are borborygmus, cramp, colic, pains, mucous blood, and pus—singly or combined—in the movement, alternating, diarrhea and constipation, feeling of incomplete emptying of the bowels after a movement. Localization of pain, or rather soreness or uneasiness. Painful spot on pressure, evidence of a tumor upon palpation or inspection, and finally—in those above the rectosigmoidal zone, an obstruction.

Physical depression, some indigestion, so called and characterized by rumbling, belching, and sense of weight. A loss of weight, slow or rapid, barring such weight depreciating diseases as diabetes and Bright's would, with the above symptoms, be an almost positive factor in the diagnosis of malignancy of the colon.

The examination of the patient must consist of a careful history, abdominal palpation for tumor of the colonic zones and the region of the liver, this last region for metastases.

The anus is then to be investigated, first with the

*Read before the Bellevue Alumni Association, March 5, 1913.

finger, and in the absence of a reachable evidence, the proctoscope should be used. Should evidence of a tumor still be absent with such a history the x-ray, with bismuth injections, is most essential. Examination of the feces for occult blood, while proving nothing definite if positive, nevertheless makes a step onward in reaching a diagnosis.

On two occasions "malignancy somewhere in the colon" was diagnosticated by finding tumor cells and polyp-like tumors in the feces. Both of these were in the sigmoid, and in each instance in the convex border of the loop, well out of the reach of the proctoscope, and only "suspicions of stenosis" reported by the x-ray. Both of these patients are living after a primary resection with end-to-end anastomosis.

In some of these growth additional symptoms were given, as pain in the sciatic distribution, well marked in the calf of the leg and sacrococcygeal pain. Frequency of urination and hypogastric pain, in this instance due to the tumor pressing upon and adhering to the fundus of the bladder.

Treatment is one of palliation in those too far advanced to operate. Palliative treatment in those of the lower bowel consists of proper cartharsis, so to liquefy the stool as to allow of its discharge through the constricted area.

The cleansing of the bowel from below by bland and frequently used enemas or injections. Such diet as will not form excess waste material. Diet free from cellulose coverings, such as prunes, corn, beans, etc.

One obstruction operated upon by me was due to a piece of prune skin so covering the narrow opening as to completely block even fluids. Another was obstructed by one of the vertebra of a chicken's neck. This piece of bone was wedged in the opening, requiring some pressure from below in the removed section to displace it. Then we must consider palliative operations, those of curettage and cautery, to enlarge the channel. Recently I have had one patient under the use of high frequency by Dr. Joseph McCarthy, and am satisfied that the patient's growth was reduced to such a degree as to make the exit of feces far more easy and painless.

Anodynes and local anesthetics, beginning with the mildest and working up to the opiates, as a dernier resort.

Operative Treatment resolves itself into resection with various types of anastomoses or short circuiting. This latter, while not curative and only a makeshift surgical procedure, nevertheless must be considered in patients in whom the tumor is of such extent as to preclude excision. When a sidetracking or short circuiting can be done to prolong life it has been followed in numbers of patients by most satisfactory and surprising results; surprising results due very often to the fact that all malignancies clinically so diagnosed are not such microscopically or constitutionally, and one must also say that all microscopically malignant tumors are not proven so by time.

Again, short circuiting may be followed by such an improvement on the patient's part and also as to the conditions of the tumor and surrounding tissues as to allow of a later day satisfactory and successful removal.

Excisions.—While 50 per cent. of the fluids and 10 per cent. of the solids of the colon are absorbed by the gut proximal to the splenic flexure, conservatism in this section must not be practised at the expense of any recurrence. Wide excisions must be practised in the cecal and transverse colonic regions, owing to the lymphatic and vascular arrangement.

In growths of the cecum it is advisable to remove the distal 6 to 12 inches of the ileum, and all the ascending colon, while in the transverse colon one should go to either flexure and pay close attention also to the glands in the transverse mesocolon and pancreatic area.

If upon exposure of the abdomen metastases be found in the liver radical removal is contraindicated.

The removal of any part of the colon is easily accomplished if one but remembers that the outer plate of peritoneum making up the mesocolon, etc., is the hold fast, that the inner is long and freely movable covering the vessels of the mesentery which arise from or pass to the median line. Therefore incising the outer plate of the peritoneum, named above "the hold fast layer," will allow the intestine to be pushed towards the median line, or even out of the abdomen with great case. Free incisions of both peritoneal plates or coverings is necessary for freeing the sigmoid; one is startled with what ease an exceptionally bound down gut can be elevated when this procedure has been properly done.

The incision of these peritoneal coverings will also allow of the vessels of the mesentery to come fully into view so that they can readily be clamped or ligated when desired. Cutting the costocolic ligament in the splenic region will allow this angle to drop well down into the abdomen.

Anastomoses.—The ease, facility, and cleanliness with which lateral anastomosis can be done makes it a most desirable method. Nevertheless, end-to-end anastomosis is the ideal method. I believe the resection cases are better handled in complete obstruction in a two or three-stage operation and know that the mortality is less.

The preliminary colostomy or short circuiting not only gives one a relatively clean bowel to work upon, but one also in which the two ends have been made nearly equal in lumen and in wall thickening. The colostomy or short circuit gives one a free vent, while the anastomosis is repairing, thereby relieving the line of suture of considerable strain.

When complete obstruction is not present the bowel can be cleaned and so prepared that an immediate or ideal anastomosis can be done with great safety. So far I have found no occasion for doing the Mikulicz three-stage operation.

Operations in the rectosigmoid and rectum present many difficulties to the surgeon and patient alike.

Our failures in these operations, which, of necessity, are operations of magnitude, are due to sloughing of the sigmoid in the anemic area, found quite frequently as a result of impaired anastomosis between the lower sigmoid and superior hemorrhoidal vessels. This area cannot always be demonstrated at the time of operation and therefore sloughing occurs just about the time we are congratulating ourselves that the patient is making a beautiful recovery.

Another of the difficulties in tumors of this area of the colon is the inability to promise our patients anything but an artificial anus, with all its disagreeable aspects and a loss of control of the anus in numbers of the resections with anastomosis.

In operations in the lower sigmoid, or the rectosigmoidal region, it is necessary that the patient give his consent to the formation of a permanent colostomy, and this preferably in the abdominal wall, having also been given to understand that if

possible an anastomosis with preservation of the sphincter will be done.

All such operations to-day are approached in one of three ways, either the abdominal or anterior, the perineal or posterior, or the combined, the abdominoperineal. Such approaches are made usually with a preliminary artificial anus.

The artificial anus is made in the highest portion of the sigmoid, so that adhesions formed by suture of the gut to the peritoneum will not hinder the dragging down of sufficient sigmoid to make the anastomosis.

These colostomies serve a double purpose. While opening the abdominal wall for the colostomies, one explores for metastasis of the liver, etc., and observes the extent to which the disease involves the peritoneal cavity. By such findings one determines whether the patient's condition of malignancy is too far advanced to proceed with a radical operation with anastomosis and preservation of the sphincter, or whether one excises the entire lower segment, making a permanent colostomy by suturing the proximal portion in the abdominal wound, or refrains from any resection whatsoever, doing only a colostomy.

The second purpose of the artificial anus is that of cleansing the bowel from above the point of obstruction, so that we have clean and relatively normal tissue for anastomosis, and that during the repair of the suture line infection and strain by means of feces and gas be relieved. Should it be decided that resection with anastomisis be done the combined abdominal and perineal operation is advised.

In the lower segment growths, and particularly in fat subjects, the posterior operation will give the best means of approach and least shock, with usually the best area of exposure; but we must remember that in these operations, as in vaginal hysterectomies, one sees and feels only a fair amount of diseased tissue. It is striking to what extent the lymphatics in the sacral and pelvic fossa are involved. Recently I did an abdominal excision, in which the glands were so generally involved that dissection well beyond the pelvic brim was necessary.

In the abdominal resection cases it is advisable to make a posterior drain between the sphincter and the coccyx by a stab puncture, placing the drainage material posterior to the anastomosed area.

Peck's operation of telescoping the sigmoid through the anus after denuding the mucous membrane from the anal portion has been quite an addition to our surgery of this region.

The method of stitching in a tube to the line of anastomosis, as advised by Gibson, and then using the tube as a means of producing an intussusception, will be found of great benefit in selected cases.

I have lately been in the habit of placing a rectal tube with its point about two inches above the anastomosis and then fastening it in the sphincter by a silk worm gut stitch. This procedure allows of the discharge of gas and liquid feces from the proximal portion. The tube is retained from five to seven days, when an enema is given to liquify any feces above; the tube is left in a day or two longer, thereby being an advisable means of sewerage and irrigation.

The retaining of the sphincter is to me a most questionable procedure, especially in the mid-rectal and rectosigmoidal region. I do not feel that these growths are sufficiently localized to retain the sphincter and the inch and a half of rectum or anus necessary for such procedure.

If one is operating upon the breast, a zone of 2-4 inches away from the malignancy is not considered too great to be excised. Why should we attempt, therefore, to save a tissue within two inches or even four inches that is so richly supplied with vessels and lymphatics as in the lower colonic region?

While it is true that the comfort, etc., of a poorly operating sphincter far exceeds a colostomy with its features, nevertheless a colostomy, with years more of possible life, is preferable to such a sphincter with but a few months to a few years. The desire to retain a functionating sphincter or an imperfect sphincter is more than likely to bias, unfortunately, our judgment in the amount to be excised.

It is in this class of involvements that I am more and more inclined to do the abdominal excision of the growth, beginning well up in the sigmoid. The steps consist in ligating the superior hemorrhoidal and branches of the upper sigmoid arteries, dissecting off the peritoneum from each side of the mesosigmoid, enucleating all fat and glands with the gut in a mass. This latter can be done with ease by

FIG. 1.—Operating position; the table should be tipped instead of level as here shown.

blunt dissection with the hand until the vesicorectal pouch is reached. The peritoneum at this point is then cut across, the bladder pushed up and forward, and then the muscular attachments in the pelvic floor are cut or torn, requiring from one to two ligatures at the most. The sigmoid is now tied at its point for excision with two ligatures and cut between; the distal end is cauterized with carbolic and is dropped into the pelvis; the proximal portion previously tied or clamped is drawn upward out of the way, the peritoneum replaced as well as possible over the dropped distal portion, the proximal end is stitched in the abdominal wall for a permanent colostomy with a few stitches only.

The patient is then placed in the lithotomy position and the anus is circumscribed with a knife or scissors and dissected out completely. Through this perineal gap or opening the distal or excised portion is then drawn, drainage placed in, etc. The colostomy is kept closed by either the ligature or clamp procedure for a couple of days, providing that no great distention be present. By this time adhesions to the side wall are thorough and the clamp or ligature may be removed.

Those cases involving the anus, with or without

extension into the rectum, and those involving the rectum, we have but one way of approach, unless we desire to make an inguinal colostomy, and that is by the posterior route. The patient is placed in the elevated lithotomy or abdominal position.

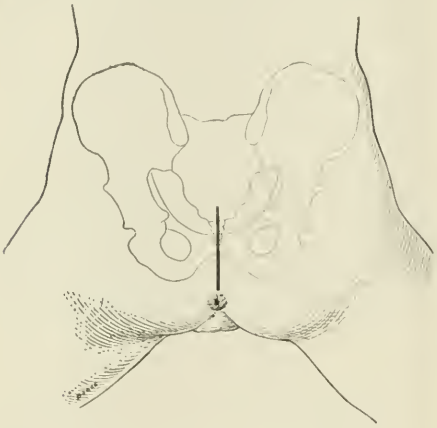

Fig. 2.—The line of incision.

For twelve years I have been using the abdominal position for all my lower rectal work. The patient is placed on his abdomen, his thighs flexed over the end of the table, the thighs separated so that the operator can stand between them, the table slightly elevated as for a Trendelenburg position (Fig. 1).

The incision is then made in the median line as high as the third sacral vertebra and down to the anus surrounding it (Fig. 2). This position will be found a most excellent one for exposure and rapid

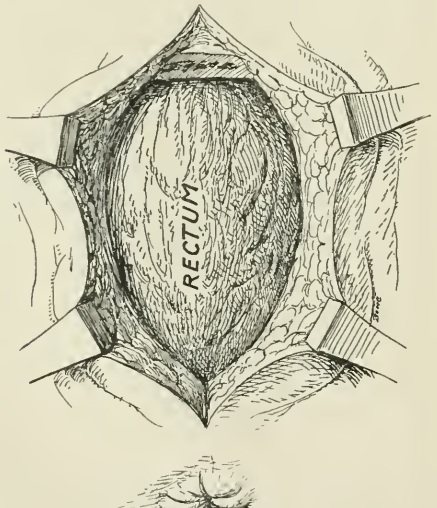

Fig. 3.—Exposure of the rectum.

delivery of the bowel. Excision of the lower sigmoid with anastomosis has been done by me with this position in many instances with great ease and freedom.

In reviewing the postoperative histories in these eighty-five patients I cannot say that I am satisfied or pleased. While true that one patient lived nine years, and that it is too early to judge the records during the past three years in the forty patients operated on in that time, it is also true that a great number have not had the relief that we wished for. That recurrences were too early in the majority of patients, or that metastasis, with death, followed far too soon.

Our greatest difficulty to-day is one of inability to diagnose early, or one of delayed diagnosis, and one without question of conservatism of function at the expense of too little removed tissue.

60 West Fifty-second Street.

STUTTERING AND ITS TREATMENT.

By FRANK A. BRYANT, M.D.,

NEW YORK.

Human speech is the result of mental stimuli and muscular movements which give expression to thought. In early infancy its rudimentary form is the exponent of an entirely natural condition due to those intimate relations between brain and muscle called congenital reflexes, and whose influences extend into adolescent and adult life to a greater or lesser degree. These forces are autokinetic, and demonstrations of their power in the genesis of speech are analogous to expressions of the face indicating joy or pain, or the taste of bitterness and acidity. In a higher degree crying, laughing, and involuntary exclamations are instances of the influence of natural reflexes.

These early efforts of infant speech arising from unconscious impulses are instigated by feelings and emotions which gradually become elevated into intelligent conceptions and real thoughts. Later, under the direction of training, mimicry, and other outside influences, the outward expression of these cognate impulses becomes intentional, orderly, systematic, and intelligible to others. If the early attempts to speak were left untrained the process would go on just the same, but the child would develop a language of its own as an outlet for its natural stimuli. An act of comprehensible speech requires merely a calling together of trained reflexes in a coordinated effort.

Speech as an expression of human thought is accomplished by means of gestures and the utterance of words and sentences. It is an outward delineation or series of pictures of what transpires in the mind. Words, sentences, and gestures are, therefore, pictorial symbols of ideas. Applying a medical term, speech is a symptom of the mental state, revealing to a nice degree whether it be keen and lively or dull and sluggish, normal or abnormal. Undeveloped, disturbed, or diseased mental conditions are portrayed quite as plainly as normal ones. Speech itself becomes pathological when mental conditions are such as to interfere with or prevent its production as a spontaneous and independent act. Under the term lalopathy are grouped the various forms of speech disturbances, some of which may be here enumerated and described.

Dysphasia.—As an autonomous process speech consists of two factors, namely, diction and articulation. Diction is an intellectual act by means of which words are chosen and grammatically arranged into sentences to give expression to thought. Inability to do this normally is termed dysphasia. Severe forms of dysphasia, such as occur in pathological conditions of the cortex, producing a motor inability to form words are called aphasias. If

added to this there exists an incapacity for the recollection of words or sounds as thought symbols, the derangement is known as amnesic aphasia. Such impairments of speech are logoneuroses.

Dysarthria.—Articulation is a motor act executed by the external organs of speech, assisted and controlled by the central and peripheral nervous mechanism through which the various movements take place, the product of which is the enunciation of sounds, syllables, and words. Disturbance of this function, or a lesion in articulaton, is spoken of as dysarthria, or anarthria. If in consequence of such a derangement a spasmodic state of speech is produced, the affection is a laloneurosis.

Dyslalia.—Defective speech produced by gross mechanical lesions in the articulating apparatus, such as harelip, cleft palate, imperfect dentition, or injury to the motor nerves, is designated dyslalia, in differentiation from the true or central dysarthroses due to organic brain lesion. Alalia is a condition of impaired articulation due to a partial or complete paralysis of the muscles of speech.

Common Forms of Lalopathy.—Stammering, stuttering, apthongia, spasmodic hesitation, and "nervous speech" belong to the domain of lalopathy. They are all either laloneuroses or logoneuroses, and may be both. Taking up the definitions and distinctions of stuttering (dysarthria syllabaris spasmodica) and stammering (dysarthria literalis) as the most important of the forms of lalopathy which we wish to consider, it is found that there is a diffent opinion held by many authors in America and England from that of the French and German scientists.

The Century Dictionary defines the terms by stating: "He who stammers has great difficulty in uttering anything; the result is, broken and inarticulate sounds that seem to stick in the mouth and sometimes completely suppress voice. He who stutters makes sounds that are not what he desires to make and the result is a quick repetition of some one sound that is initial in a word that the person desires to utter, as c-c-c-catch." Other English dictionaries give about the same definition, which thus classes both stuttering and stammering as disorders due to a muscular spasm. The inference is that stuttering is a mild form of stammering.

The French and German authorities place only stuttering in the spasomodic class. Stammering is used to describe all anomalous conditions where there is inability to enunciate certain sounds or letters correctly. Stammering, they maintain, is constant, while stuttering is intermittent.

A further comparative description of these disorders under the German system[1] will be interesting to some and may be made as follows. The stutterer can make all the separate sounds used in speech when isolated. The stammerer cannot pronounce his difficult sounds correctly at any time. It is only when the sounds are joined syllabically in the endeavor to produce words which contain thought, that the stutterer has difficulty, and not always even then. The stammerer will show the defect whenever and wherever certain sounds or letters occur. The stammerer is most likely to have trouble, which is constant, with such letters as *r, l, s, th,* and other double consonants; while for the stutterer these somewhat continuous sounds are generally easier than the explosive consonants.

In stammering the speech is defective because the movements of the organs are mechanically incorrect in regard to position. In stuttering the movements are correct as to position, but deficient as to time and force. In stammering the peculiar spasms, contortions, and gasping seen in stuttering are absent. The nervous embarrassment and confusion (lalophobia), followed by depression, which is a marked feature of stuttering, is not experienced in uncomplicated cases of stammering. The broken rhythm or lack of proportion between the vocal and phonetic processes, a sort of respiratory delay, which is prominent in stuttering, does not occur in stammering. The stutterer can always pronounce the words correctly in singing, but the stammerer cannot. The practice of melodic and rhythmical sounds and exercises exerts a beneficial influence on the stutterer's condition, but has no effect whatever on that of the stammerer. Stammering is frequently accompanied by and caused by organic defects, malformations and paralyses which are rarely seen in stuttering.

Causes of Stuttering.—It is often impossible to discover any cause for stuttering. In fact the cause may have long since passed away, but its effects remain in the form of a habit, either mental or physical, or both. Most cases depend probably upon an exaggerated irritability of the natural reflexes associated with the spontaneous production of speech. There can be no doubt but that *phylogenetic influences* play an important part in causing stuttering. Children inherit other mental and physical characteristics, and statistics support the statement that there are more persons who stutter that have had relatives which were similarly afflicted than any other class. The element of association and a sort of resultant psychical contagion in such cases must, of course, be taken into account, but other reasons point to consanguinity as the greater force. For instance, cousins who have not been associated, often stutter or have some nervous speech trouble. Grandchildren are frequently affected who have never seen the grandfather or grandmother who stuttered. The speech of nephews and nieces is likewise often impaired. Many cases of this sort of atavism have been seen which seemed to have skipped one or more generations.

Case I.—A man who lived to be eighty years of age was a stutterer from childhood. The cause of his impediment could not be ascertained. He had two sons, Robert and Henry. Robert, the elder by three years, was a stutterer from the age of three and a half years. The mother stated that he had no difficulty when he began to speak for about two years, when the impediment appeared rather suddenly. He grew to manhood a stutterer, married, and had two or three children none of whom was afflicted. One of these children, William by name, also married and had several children, two of whom began to stutter before they were five years of age. It had skipped the grandson William to show again in the great grandchildren. Henry, the younger son of the original stutterer, although constantly associated with his stuttering father and his stuttering brother Robert, did not contract the malady, but curiously enough, his son James became a severe stutterer. This son James, whose father Henry was skipped, was a grandson of the original. Another son of Henry who was not affected has one boy who, though now quite young, hesitates in his speech and shows decided symptoms of stuttering. Here again the hereditary influence is seen in the fourth generation after skipping the second and third in a direct line, although the uncle, James, of this young boy was a stutterer in the third generation.

The individuals referred to in this case were all native born, intelligent Americans, enjoyed good health otherwise, had no stigmata, no bad habits, were not "nervous" people, and occupied places in business and professional life rather above the average. The facts as here related were all investigated by the author, who saw all the persons mentioned.

and records them here as a rather remarkable example of the principle of heredity in causing stuttering.

The next two important causes which have been instrumental in producing stuttering are *imitation* and *fear*. Many young stutterers have become so from mimicing a stuttering companion in a spirit of fun or ridicule. If done unkindly, it surely brings its own punishment and the victim gets and perhaps deserves little sympathy from others. A more serious kind of imitation is that where it is done involuntarily, as is likely to be the case in the close association of home and school. There are many children whose sympathies are so easily awakened by beholding instances of suffering, whose mental conditions are so plastic that when they see another child struggling over a word, they themselves actually experience the same feeling through a sort of sympathetic contagion and soon show the same difficulty in attempting to speak under mental strain or embarrassment. It is a singular fact that bad habits of speech, the use of incorrect grammar, slang, profanity and other undesirable modes of expression are much easier learned and longer retained by humanity in general than are good habits and the language of refinement and culture.

Sudden fright in childhood is another very fruitful cause of stuttering. That portion of the medulla oblongata which regulates the functions of the respiratory and vocal apparatus, when severely shaken by some powerful psychical impression in childhood, such as abject fear, transmits a shock to the nervous system that is liable to excite incoordinate movements, especially of the speech muscles. This disorganization in the medulla may extend to the processes of neighboring nerve nuclei and call into action accessory spasmodic movements of the muscles of the face, eyes, tongue, and neck, and not infrequently those of the arms and legs. Among the many cases seen two deserve especial mention, in both of which there was excessive fear, although in one of the cases there was no real danger.

Case II.—A group of children were playing at a friend's house. In the course of their sports one of the older boys dressed himself in ragged clothing to resemble a tramp and appeared suddenly before the others wearing a hideous face or mask. On seeing this ugly and horrid image one of the little boys, a child of four years of age, uttered a piercing scream and as he started to run away with the others fell upon the floor. He became unconscious at once and remained in convulsions more or less constant for several hours. He had previously been a good talker for one of his age, but after this experience he lost the power of speech entirely and seemed in a semi-dazed condition for ten days or two weeks. When he did commence to speak again it was with difficulty that he could make himself understood. Pronounced stuttering soon appeared. He grew up a healthy child, but a confirmed stutterer.

Case III.—A very healthy, robust boy of eight years of age was taken during the summer vacation to the seashore with his parents. One day his father, to whom he was much attached, and some friends went fishing on the ocean in a small boat, leaving the boy at the hotel with his mother. When it was time for the father to return, the boy and his mother walked down to the beach to greet him. The surf was very high and strong, and as the boat containing the father approached the shore it was caught in the breakers and overturned. The boy on shore saw his father thrown into the water, heard his frenzied cries for help, saw him drawn under by the powerful and swift undertow, and realized that his father was in great danger of drowning. Fortunately, life savers were at hand and the father's body, more dead than alive, was brought on shore and resuscitated. When the boy saw his father disappear under the waves he fainted, but recovered in time to see the apparently dead body brought out of the water. Subsequently he watched with great anxiety the efforts at resuscitation which were finally successful. This terrifying spectacle and experience gave him a profound nervous shock and in the course of a few days, from a lad who had always spoken fluently, he began to stutter, and later developed a most severe type of mute, gutturotetanic stuttering.

Numerous other interesting cases could be cited where the nervous instability incidental to excessive fear had so unbalanced the harmonious relations which exist normally between the brain and the speech organs that disordered speech resulted.

Valuable information upon the morphological changes that the brain cells undergo in shock produced by fear has been acquired by the recent investigations and experiments of Crile. In an article on "The Kinetic Theory of Shock, etc.," published in the *Lancet* of July 5, 1913, he says: "According to my kinetic theory of shock, the essential lesions are in the brain cells, and are caused by the conversion of potential energy in the brain cells into kinetic energy at the expense of certain chemical compounds stored in the cells. It is a physical law that no energy can be lost, and every adequate stimulus must, therefore, receive its adequate response. Where, then, shall we look for the part which is exhausted under the strain of too great stimulation? Since we find that those animals which suffer most from shock are those with the most highly developed power of associaton memory, we should expect to find the greatest ultimate damage in the centre of the mechanism for this faculty. This damage may be sufficient to break down the cells at once, and we have a general exhaustion; or the cells have become so overcharged that slight additional stimuli will be sufficient to overbalance them and we see the after effects of nervous symptoms. The cells in the cortex of animals exhausted by fright or by physical trauma showed like changes, and these morphological changes, varied from slight alterations in the cell contents to complete deterioration.

"This theory assumes (1) that the environment of phylogeny (ancestral history) through adaptation predetermines the environmental reactions of the present; (2) that in each individual at a given time there is a limited amount of potential energy stored in each brain cell, that is, that the cell contents under stimulation are capable of a certain amount of chemical change, which will produce a relative amount of action—kinetic energy; (3) that the motor activity following each stimulus—traumatic or psychic-diminishes in some degree the amount of potential energy in the brain cells, that is, by some chemical change of the cell contents a certain amount of kinetic energy is produced and a certain amount of reserve power is lost; (4) that when the motor activity resulting from the change of the potential energy in the brain cell to kinetic energy takes the form of obvious work performed the phenomena expressing the depletion of the vital forces are termed physical exhaustion; (5) that when the expenditure of energy caused by emotional stimuli cannot take its normal course and produce motor activity, the condition reacts upon the cell itself. The stimulation is thus automatically increased and the resultant expenditure of potential energy is proportionately active.

"And here it may be noted that the final result of intense fear is the same as that of physical exhaustion or that following psychic strain, and that it is a primary and most far-reaching fact—namely,

that the animals (and persons) most capable of being shocked are those whose self-preservation is dependent upon some form of motor activity and in whom the presence of bodily danger is capable of producing the phenomenon of fear."

Assuming this postulate to be correct, it is easy to understand how fright and fear deplete and shatter the potential energy of the brain cells to such a degree that the intricate and orderly changes essential to an act of normal speech are impossible and which may keep it so until a confirmed habit is the ultimate result. This knowledge of how fear, psychic strain and mental shock affect the cell content throws a great deal of light upon one of the chief and invariable characteristics of stuttering. In stuttering the remembrance of former failures produces a constant dread and fear of future difficulty, which in most sufferers is a greater mental stram than the fear of a moderate degree of bodily harm would be. This application of Crile's theory, which is wholly tenable, explains to some extent why this chronic state of fear keeps the physical force and energy of the brain at such a low ebb that, notwithstanding a strong desire to speak and a clear intellectuality, the individual is incapable of doing that which all his other mental faculties tell him he should be able to do—actually anaphasia.

The other causes that have been mentioned as conducive to stuttering are probably about equal in frequency and importance. Harshness and fear of punishment at home and in school as a contributing factor, however, should be emphasized because it can be avoided. It is positively dangerous and unpardonable to speak harshly to a nervous child, and to punish when in a fit of temper as is too often done, involves the possibility of entailing upon the little one a lifelong burden of deranged speech that will seriously impair its usefulness and happiness in every station in life.

Inception of Stuttering.—Most instances of disordered speech begin in early childhood before the age of seven years. A few show the affection soon after beginning to speak, especially if there have been convulsions in earlier babyhood or where there is a hereditary predisposition present. Usually, however, there is a period of normal speech of from one to five years after the child has begun to form sentences. This being the case, coupled with the fact that at times all words are uttered plainly even after the child has begun to stutter, indicates that there is no malformation or organic defect in the speech organs themselves.

It is not until the mind has developed sufficiently for the child to take an interest in the affairs of life that the trouble manifests itself. Up to this time the workings of the natural reflexes have enabled it to repeat the sounds and words it has heard; but as soon as the individuality asserts itself, then a desire to express its own particular thoughts brings new factors into the creation and transmission of the speech impulses. Interest and eagerness to communicate ideas then throw such an amount of nervous excitement and force upon the tiny muscles of the undeveloped speech organs that they are overwhelmed. They cannot perform their normal functions at a rate of speed and precision proportionate to the amount and character of the stimuli received and hence confusion and disorder result.

It is nearly always the highly organized, sensitive child whose intellectual and emotional faculties develop earlier than the corresponding physical conditions that shows stuttering in early childhood. Soon this lack of control occurs every time an unusual mental emotion seeks an outlet in speech. Thus a spasm habit is formed, chiefly mental, but in some degree and in a connecting manner physical, which as often as it is repeated grows stronger, so that if mental aberrations be absent, a muscle habit remains.

It is a reasonable assumption that these frequent derangements change to some extent the chemical content if not the structure of the brain cell and through deterioration of cell, ganglion and fibre the amount and force of the transmission of kinetic energy through normal paths, especially when an almost constant dread and fear of failure is present. It is certain that in the habitual stutterer that portion of the brain concerned in the act of speech is more easily excited than in ordinary individuals.

With this state of abnormal sensitiveness and excitability of the cells in what may be called the ideational region of the brain, in the adult as well as in the child, it is not strange that during the orgination and transmission of the speech impulse to the motor centers and thence to the speech organs themselves that inhibition of the natural reflexes occur and control is lost. Evidently, the trouble is due to the character and influence of the thought impulse, and its origin is just where the mental processes take hold of the physical apparatus and where the mind and body interlace in the executive department of the speech economy.

Causation of Other Diseases.—There are, however, other diseased conditions of the body which stuttering is liable to bring on, which are of sufficient importance to consider briefly. Passing over with only a brief mention the deleterious effects of confirmed and protracted stuttering on the nervous system in the production of neurasthenia, hypochondria, and melancholia, it is a fact that the shallow and intermittent respiration peculiar to this habit fails to aerate the lungs properly and exposes the sufferers not only to lung diseases but to all other morbid conditions resultant upon insufficiently oxygenated and impure blood.

In further proof of this assertion, statistics from an industrial school in England[2] show that the breathing capacity in a group of stuttering boys (nine cases) of twelve and thirteen years of age, the average was 88 and 109 cubic inches respectively; whereas an examination of a like number of non-stutterers of the same age gave 166 cubic inches as the average. There is also no doubt but in consequence of the disturbances in the circulation of the blood in cases where there are frequent severe spasms and violent exertions to speak, a predisposition to apoplexy, valvular diseases of the heart, and aneurysms of the aorta and large blood vessels of the upper chest and neck is produced.

Prognosis.—The prognosis of untreated stuttering is variable. Much depends upon the age, health, and temperament of the individual, upon his associations and environment and upon the causes, form, duration, and degree of the affection. Occasionally light grades disappear spontaneously during late childhood and adolescent life. This has been noticed to be the case where children had been kept on an insufficient and innutritiious diet, that when given adequate and proper nourishment the infirmity disappeared. Experience does not prove, however, that a majority of children who are affected outgrow the difficulty.

Prognosis is said to be unfavorable under the following conditions, viz., when there is a heredi-

tary predisposition to the affection, or where there is great irritability of the congenital reflexes or weakness of coordination generally when the trouble is of a severe form and has lasted a long time; when spasms of the glottis and its muscles are a predominant feature; when the contractions extend to groups of muscles other than those involved in the immediate production of speech; when there is lack of ordinary intelligence or instability of thought and purpose, and when the patient is advanced in age.

Treatment.—The treatment of stuttering is attended with many difficulties. It is doubtful whether there is any treatment for confirmed cases which is entirely curative. Impediments of speech have existed as long as the history of mankind. Some of the best qualified psychologists and specialists of every age and generation have been interested in their cure. Itard stated in 1817 that the treatment of stuttering had made no progress in two thousand years. The results attained by the specialists of the present day and the recent literature upon the subject do not indicate that anything nearer a specific cure has been found.

It is probably better that the public should be told this by those who ought to know. It would prevent much misapprehension and disappointment because there are reasons for thinking that a belief exists among the uninformed that there is a sure cure in the methods of this or that person. The public generally should know that in spite of extravagant claims, there is a sense in which a cure of inveterate stuttering is never complete. A person who has once developed such a case, although he may be apparently cured and able to speak well is never quite the same as one who has never been afflicted in this way. Relapses, too, are common. Without constant care and the most favorable conditions, the malady is liable to recur to a greater or less degree.

This discouraging prognosis, however, should not be a cause for despondency or a do-nothing attitude. It would be a rash and unreliable promise that would hold out hopes of a positive cure in every case of stuttering, but because we cannot in every instance accomplish all that we wish, is no reason why we should stand idly by and do nothing. Because as yet we cannot cure every case of tuberculosis, nephritis, or gastritis we do not throw up our hands, so to speak, and cease our efforts to do what we can. It is well known that many cases of the above disease have been practically cured when the treatment has been begun early in the history of the affection and carried out wisely and persistently.

While the affliction of stuttering is not often a matter of life and death, yet that it is a dire misfortune no one will deny. To ignore and neglect the needy condition of persons afflicted in this way because we are not sure of making an absolute and permanent cure in every case is on a par with the proposition to neglect the sick because all do not get well under treatment. It is a fact that, even with our present knowledge and remedies, there are thousands of children and young people who have been and who can be educated and trained so that their impediments will give them very little trouble and will in time grow less and less, according to the care, application, and perseverance that they exercise. Even if the treatment of stuttering, as is often the case in other diseases, is attempted frequently by irresponsible persons, who seek to deceive with false promises, worthless remedies, and tricks, this should not deter reputable men from making persistent attempts to relieve this worthy class of innocent sufferers who absolutely need and should have the best efforts of able and conscientious physicians, teachers, and philanthropic persons.

Prophylactic Treatment.—The worst has now been said about what cannot be done or expected and the way has been cleared for a better understanding of what can and should be done. In the first place, prophylactic treatment is of the utmost importance. It necessarily must be commenced in early childhood. It probably would be more efficient if it could be begun with grandparents. Childhood is the time *par excellence* to ward off and even to cure stuttering.

It is an axiom in the proper supervision of the health of all children that their noses and throats should be examined by competent medical men for the purpose of correcting abnormal conditions in and about these organs. It cannot be said that the presence of adenoids and enlarged tonsils are a cause of stuttering or that their removal will cure it. There are thousands of children who have these obstructions who do not develop stuttering, but inasmuch as deficient and delayed respiration is one of the chief causes, an obstructed respiratory tract is directly contributory to a shallow and unhealthy manner of breathing.

Obstructions to the air current if they exist should be removed and the child trained to breathe through the nose. Not only should it be taught to inhale and exhale through the nostrils, but also to breathe slowly and deeply continuously as a matter of habit. Efforts should be made to expand the lower part of the lungs, which are covered by the inferior thoracic and waist muscles, and to induce free excursions of the diaphragm. This style of breathing will serve to quiet nervousness, insure better control and prove more healthful and helpful than clavicular or chest breathing.

A child for whom stuttering is feared should not be allowed to make attempts to speak under great excitement, nor when laughing or crying, and especially not during the paroxysms of whooping-cough, because at these times the natural rhythm and force of the respiratory function are deranged. For the same reasons, tickling a child is a dangerous practice.

Since stuttering is a neurosis, causes of nervous irritation should be removed as far as possible and kept away from a child who needs protection in this respect. Constant worrying or teasing, even in a friendly manner, is apt to foster a nervous excitability which is conducive to stuttering. Undue severity may be another contributuory cause which should be guarded against. There are some other physical conditions which help to make a child nervous, for which a physician's advice and service should be sought.

When the breathing and the nervous conditions have been made as good as they can be, it is important that every effort be made to keep the body in as sound and vigorous a condition as possible. Good food and nourishment at proper intervals, pure air in sleeping rooms, early retiring, a quiet darkened room in which to sleep, cleanliness of person especially of the mouth and teeth, moderate forms of play, exercise or work are all most useful in keeping the system in a condition to resist the onset of nervous speech troubles.

Not all of these measures perhaps would be needed in every case, but there is one other very useful prophylactic suggestion which will apply to all cases where stuttering is feared or where an effort is being made to check the habit. It is that of always exhibiting before the little one a model of perfect speech as an example for it to follow, both consciously and involuntarily. Children learn to talk largely from imitation and it is therefore very important that they should have a good form to copy.

In this connection much assistance can be given by maintaining an explanatory but persistent and strict supervision over the methods of producing sounds and words until habits of good articulation are firmly established. Exercises and experiences calculated to strengthen the character, broaden the will power, arouse the ambition in certain cases, and develop habits of application and perseverance will all be most useful in counteracting a predisposition to stuttering and even of correcting it in its earlier stages.

Curative Treatment.—Inasmuch as the causes of spasmodic seizures of speech are largely abnormalities or perversions of the mental state, it follows that proper treatment of such disorders should be mental, didactic, and pedagogic. Medical treatment, too, is frequently indicated, for, by reason of the deranged nerve function and the congested condition of the circulation common to all forms of spasms and convulsions, the general health is often affected. Minor surgical operations upon the tongue, pharynx, and nose for the purpose of correcting anomalies, are sometimes advisable.

Reference to the application of electricity is mentioned only to state that it has never proved to be of any permanent value. The same may be said of hypnotism. The sufferer may speak well while under the hypnotic spell, but its influence soon passes off and the subject feels weaker than before. The knowledge that other persons have a stronger will and that he has been made to act as an automaton is not an assuring factor in the development of an independent personal control, which is the *sine qua non* in untrammeled speech.

Psychoanalysis for the treatment of stuttering, of which a good deal has been written lately, is of little if any practical use. Recalling a stutterer's dreams may give a better idea of his waking thoughts and help to determine the motives and influences which control his conscious actions, but this information can usually be obtained in a more direct and positive manner by inspection and observation.

Mental treatment is of the greatest importance. It comprises so many things that it would be difficult to state what is not included. It takes up every phase of life that affects the feelings and emotions of the sufferer. Any and all measures which may be brought about by the physician, teacher, parent, or individual which will increase the mental poise and equilibrium are of incomparable value.

In accordance with the best treatment of other nervous disorders the mind should be led away from the stuttering *per se* and from the fact that efforts are being made to cure it, as one would treat a bodily disease. An effort should be made to think of it as a habit only, which will disappear as soon as new and better habits are installed in its place. This is best done by explaining and placing before the individual a model of perfect or normal speech, impressing upon him that he is a student of the great art of speech, and assuring him that if the rules and principles which underlie and govern normal speech are complied with, there will be no stuttering.

Among other influences which will affect the mental condition favorably may be mentioned the choosing of a pleasant environment and associations, habits of self-reliance, avoidance of and repelling depressive states of mind, resolutions to control excitement, interest, and eagerness to speak as much as possible, the development of an independent and courageous manner, and all other acts of the mind which will go to strengthen the mental stability and increase self-confidence. Any means which will help to build up and restore confidence in general will be of the greatest aid in removing the defect. The education and development of the directing powers of the mind in controlling the acts of any other group of muscles will be of assistance in gaining control over the refractory muscles of speech. For this purpose, the practice of light calisthenic and mild athletic exercises will be found very beneficial.

The *didactic and pedagogic treatment* consists in going over the technique of speech from its very simplest forms to that of the complicated utterances of the natural and perfect product. It is by this means that the coordination of the three principal physical factors of speech, namely, respiration, vocalization, and articulation are brought under control and harmonized. It has been stated already that the stutterer fails to perform the mechanical acts requisite to correct speech, especially in regard to proper time and force. The didactic method points out to him where and why he has done so. By it he is taught how and why sounds are made which eventually form words and sentences. Daily drill in graded exercises is to be carried out and to be persevered in until perfect enunciation is reached and correct habits of speech are firmly established.

In this way the physical factors of speech are properly trained, the mental component reeducated and developed and their functions so harmonized that the incoordination which caused the spasm is lost and speech becomes normal. The combined mental and didactic forms of treatment serve to impart a logical compactness and continuity to the expression of thought and thus aid in preserving the natural rhythm and force of speech, which is always broken up and destroyed by the intermittent and badly modulated style of the stutterer. General directions only can be given, for each case has its own peculiar situation and need, which should be studied carefully and such remedies adopted as appear most suitable and useful according to the circumstances.

In correcting speech disorders the oft repeated maxim of "doing the things in detail which belong to good speech in general will produce good speech" is a good one to keep always in mind. The modus operandi will sometimes tax the wisdom, ingenuity, and patience to the utmost, but abundant rewards await the resolute and tireless worker.

AN UNUSUAL CASE OF APPENDICITIS (RETROCECAL) ASSOCIATED WITH RARE ANATOMICAL ANOMALIES.

BY VINCENT ANTHONY CAPENTA, M.D.,

INDIANAPOLIS, IND.

Miss A. C. consulted me April 26 on account of a "stone in the kidney." She related that this was the fourth attack that she had experienced in the last year. Her family history is of no interest in this case. The only points of importance in her personal history were typhoid fever about ten years ago and a miscarriage with probably some pelvic peritonitis about two years ago.

Physical examination—Female, age 28, of excellent skeletal development. Temperature 100°, pulse 90, respiration 30. The face of the patient had the appearance of a prolonged toxemia, the facies peritonitica was lacking, abdomen was not at all distended, nor did the patient complain of abdominal distress. He did, however, complain of a pain in the lumbar region corresponding to the location of the right kidney.

On palpation of the right iliac region pain was elicited. There was no rigidity of the rectus muscle nor was any muscular reaction caused by the pressure. I assumed this to be a case of retrocecal appendicitis and differentiated it from renal colic by the following cardinal differential diagnostic considerations; I noted the absence of pain radiating down the course of the ureter and the absence of retraction of the right vaginal labium. The temperature curve as observed for three days was also against the diagnosis of renal colic as it evidenced the presence of pus, and as no pus was demonstrated in the urine I felt safe in assuming that the pathological lesion was located elsewhere than in the kidney.

The hematological examination revealed a leucocyte count of 14,500 and the differential examination revealed 82 per cent. polymorphonuclear neutrophiles with few eosinophiles. There was a marked iodophilia which I maintain is always very reliable evidence of absorption of bacterial toxins; I therefore felt safe in advancing a diagnosis of retrocecal appendicitis.

Operation, May 29, Deaconess Hospital. Abdomen was opened by gridiron incision and, as expected, nothing pathological anterior to the cecum was found. To my astonishment the cecum was found enveloped in a peritoneal membrane extending from above the iliocecal juncture to the end of the cecum, forming a well marked mesentery to the cecum; this membrane being strongly fixed to the posterior wall of the iliocecal fossa.

The membrane was opened and gradually dissected from the underlying cecum on both sides of the gut and to the line where it resembled a mesenteric attachment. The folds of this false mesentery were opened and the appendix was then exposed. It was a very large appendix firmly adhered to the cecum.

In this funnel-shaped envelope there was only a very small amount of pus. The appendix was dissected loose from the cecum and removed and the membrane was removed from its attachment at the posterior abdominal wall.

In my opinion this membrane enveloping and forming a false mesentery to the cecum was formed of a pair of peritoneal folds probably of fetal origin. I feel quite certain that this was not a case of membranous pericolitis, nor could these large peritoneal folds forming a distinct mesentery to the cecum be considered as the peritoneal folds described by Jonnesco and Treves.

I believe that we have in this case a rare anatomical anomaly. I refer the reader to the masterly description of the cecum by Piersol in his "Anatomy." He brings out very plainly that the cecum has no mesentery at all and describes very minutely the peritoneal folds of Jonnesco and Treves. Whether the large peritoneal folds described in this case are persistent fetal structures or the result of disease I am unable to determine. I have made a fair search of the literature and have failed to find a similar case.

Is Tobacco a Drug?—An interesting case of splitting hairs has arisen in Ireland in the administration of the National Insurance Act, as to whether tobacco is a drug, a necessity, or a luxury, all three views being taken by different authorities. It appears that the superintending medical officer of the Dublin district recommended that a consumptive patient coming under the provisions of the act be given tobacco for smoking, to comfort him in his last days, offering to pay for the weed himself, but the insurance committee decided that the tobacco was necessary to the patient's treatment and sent in the bill to the insurance commissioners. Two weeks later the local authorities received a lengthy communication demanding an explanation for their action in charging the government with a shilling's worth of tobacco. Their reply was that tobacco was recognized as a drug in the British Codex under the title nicotiana tabacum and that it had been prescribed by a registered practitioner. Thereupon the commissioners consulted learned King's counsellors and they are still wrestling with the subject. Meanwhile the patient is dead, the tobacco has been smoked and the expense of the disputation has already reached a hundred times the cost of the original tin of shag.—*American Druggist.*

A Reaction to Differentiate Human from Cow's Milk.—Bauer states that if there be added to two or three cubic centimeters of human or cow's milk one drop of a one-fourth of one per cent. watery solution of nileblue sulphate (Grübler), both specimens will be stained blue—but greenish blue in the case of cow's milk and violet blue in the case of human milk. If to either specimen there be added five times the volume of ether, and if the mixture be vigorously shaken, it will be noted that the cow's milk retains its blue color, while the human milk is decolorized.—*Monatsschrift für Kinderheilkunde.*

Treatment of Diphtheria Bacillus Carriers.—J. D. Rolleston treated ten chronic diphtheria bacillus carriers by spraying and swabbing the throat or nose with a bouillon culture of *Staphylococcus pyogenes aureus.* In six faucial cases the findings became negative within two to seven days after starting the treatment. In the two nasal cases the treatment was ineffective. In all but two cases a mild form of sore throat was produced, but no complication ensued.—*British Journal of Children's Diseases.*

The Relation of Appendicitis to Diverticulitis.—M. Guibé concludes from his observations that the simultaneous occurrence of appendicitis and diverticulitis is not infrequent. This association may be a mere coincidence or there may be a causal relation between the two conditions. Sometimes the appendicitis results from the diverticulitis, but more commonly the affection of the appendix provokes a secondary infection of Meckel's diverticulum.—*La Presse Médicale.*

MEDICAL RECORD.

New York, October 4, 1913.

MIXED INFECTION IN TYPHOID FEVER.

IN the early stages of the development of the so-called germ-theory of disease the whole matter was accepted by its subscribers as being comparatively simple. A certain kind of microorganism gained access to the body and was able to produce certain changes which we have come to know as disease. In the course of time facts have accumulated which have sufficed to alter these early views to a certain extent. We know that certain bacteria are able in themselves to produce certain diseases, but have learned that many of the changes found in these diseases may be due to a subsequent infection with some other organism which is frequently totally different from the primary infecting agent. The difficulties in the way of determining the truth in these cases are frequently tremendous, but some observations have been repeated with enough accuracy and persistency to have acquired a firm position. The cavity formation in tuberculosis is probably due to a secondary infection. A chronic urethritis may be kept going by the presence of some of the pus cocci, though originally due to the gonococcus. Many of the complications and sequelæ of scarlet fever are due to a streptococcus which is in all probability a secondary infection. The importance of mixed infection is quite universally recognized, though all the instances in which it occurs have not been demonstrated.

The belief has always been held, however, that typhoid fever is the result of infection with the *Bacillus typhosus,* and that all the pathological changes which are so characteristic of this disease are examples of the work of this organism. Recent bacteriological investigation has yielded what seems to be good evidence for the contention that in this condition also mixed infection is of great importance. J. Loris Molikoff, working under the direction of Metchnikoff (*Annales de l'Institut Pasteur*, 1913, xxvii, 541) conceived the idea that the great variations in the severity of this disease might be due to other factors than the virulence of the typhoid bacillus and took up the study of the anaërobic flora of the intestine in a large number of cases of typhoid. Using the usual methods he isolated the *B. perfringens* of Welch, the *B. III* of Rodella, and a third microorganism hitherto undescribed, which he calls the *B. satellitis.* Some of the characteristics of these organisms are interesting. In very severe cases presenting intestinal complications the strain of the *B. perfringens* isolated killed a guinea-pig in from twelve to eighteen hours, while the strains obtained from the mild cases were for the most part without effect upon this animal. The author is rather of the opinion that the virulent type constitutes a distinct variety of the perfringens. The *B. III* of Rodella is probably without significance. The *B. satellitis* as described seems to occupy a position between that of the perfringens and that of the *B. sporogenes* of Metchnikoff. In guinea-pigs killed by inoculation with this organism the Peyer's patches were swollen and ulcerated, and the lymphoid tissue in general seemed to be markedly affected. The author found this organism in nearly every case of typhoid examined, and failed to find it in the stools of fifty normal individuals. He injected guinea-pigs with various mixtures of *B. typhosus, B. perfringens,* and *B. satellitis* singly and with one or both of the others, and notes especially that though in every case the Peyer's patches were swollen, ulceration occurred only when the last-named organism was injected. As a result of his work he is inclined to divide typhoid fever into two distinct processes. One of these, a septicemia, is due to the *B. typhosus,* while the other is necrotic in type, is marked in that portion of the intestine which is most completely deprived of air, and is probably caused by the *B. satellitis.* The matter is, of course, far from settled, but so far the experiments seem to support his contentions. The most alarming complications of typhoid fever are due to this ulcerating action, and if its cause can be found to lie in a secondary infection, which in turn may be forced to yield to treatment, the outlook is good for a very marked reduction in the mortality in this disease in the not too distant future.

ARTERIOSCLEROSIS FROM A NEW VIEWPOINT.

MANY theories have been advanced to explain the origin of arteriosclerosis and all of these have fitted in more or less with known clinical and pathological data. The experimental production of arteriosclerosis by means of injections of nicotine and suprarenal extract has seemed to explain at any rate a certain percentage of the cases of this condition, but has thrown no light upon the actual chemistry or mechanism of this sequence. A novel explanation has recently been offered by G. Lemoine, who occupies the chair of clinical medicine in Lille. This hypothesis, based upon the results of laboratory experiments, is reported in the *Gazette des Praticiens,* September 1, 1913.

Lemoine has on a number of occasions advanced the theory that the lipoids rich in cholesterin have the power of diminishing the toxicity of various substances that are known to cause atheroma and arteriosclerosis. According to this view, if suprarenal extract, nicotine, or alcohol is introduced into the blood, the organism mobilizes its reserves of lipoids in order that these may be sent into the blood to neutralize the toxic substances. Being but slightly soluble, cholestrein, after having fulfilled

its antitoxic function, is deposited upon the arterial wall in the form of plaques of atheroma. Lemoine has already shown that the injection of lipoids into animals that have already received an injection of suprarenal extract causes a marked diminution in the toxicity of the latter. Later experiments demonstrated that the same result can be obtained if nicotine is used as the toxic agent. The animals experimented upon were guinea-pigs. The oxalate of nicotine was employed, as being the least toxic of the salts of this substance. The minimum lethal dose of the former was found to be 7½ milligrams for each 100 grams of the animal's weight. If in conjunction with this lethal dose there was injected into the guinea-pig a dose of 5 milligrams of lipoids extracted from the bodily organs death did not result. Lipoids extracted from the lung were particularly efficacious in neutralizing the toxicity of nicotine. These experiments give an apparently conclusive demonstration of the antitoxic action of the lipoids. According to Lemoine, these bodies counteract the slow intoxication associated with the habitual use of tobacco. If this use is excessive a relatively large amount of lipoids is summoned to the blood stream. After having fulfilled their antitoxic function these substances are then deposited as atheromatous patches on the arterial wall.

This conception of the morbid physiology of arteriosclerosis is certainly an ingenious one, and must be seriously considered in view of the experimental foundations upon which it is established. It is fully in accord with the newer teachings concerning the important rôle played by the hormones in the protective mechanisms of the body. Moreover, this theory is pregnant with therapeutic indications. It emphasizes particularly the importance of prophylaxis—the avoidance of those toxic agents that are known to produce arteriosclerosis. Lemoine believes that among these agents may be included iodide of potassium, a drug that has actually been used for a long time as the sovereign remedy in combating arteriosclerosis. Thévenot of Lyons has succeeded in producing in animals an arterial atheroma by means of the prolonged administration of potassium iodide. The use of this drug in arteriosclerosis is therefore looked upon by Lemoine as a therapeutic heresy. On the other hand he regards as rational only the use of a substance which when introduced into the organism is capable of dissolving cholesterin. Such substance he believes he has found in the phosphatids in the colloidal state, the clinical use of which seems to have given promising results.

SANITATION AND TYPHOID VACCINATION.

During the past month there has been a local epidemic of typhoid fever in this city, upward of 300 cases, largely among children, having occurred in a limited district on the East Side. An outbreak of this sort naturally attracts the attention of the public by the peculiarity of its restriction to a comparatively small area, and from the point of view of the practical sanitarian, by reason of this very fact, it offers a unique opportunity to prove to the public the value of an exhaustive scientific investigation in identifying the cause of the outbreak and explaining why it is so strictly localized. Success in this would not only demonstrate the value of such an investigation, but would also make it easier to prevent outbreaks of the kind in the future. Failure to make such an investigation or an abandonment of the search before the cause of the epidemic is positively determined would tend to weaken the faith of the public in sanitary measures as a means of prevention of infectious diseases. For this and other reasons it is regrettable that Health Commissioner Lederle should at this time have made a public statement advocating antityphoid vaccination; for, although such an idea was probably farthest from his thoughts, it will be interpreted by many as a sort of throwing up the sponge and a confession that sanitary measures are inadequate to protect a community from infectious disease.

Antityphoid inoculation is undoubtedly protective, its efficacy has been amply demonstrated in the British Army and our own, but it is an emergency measure, and it would be a calamity were the public led to believe that typhoid fever could thereby be eradicated and that sanitation had failed or was superfluous. In comparing antityphoid inoculation with vaccination against smallpox there is danger of straining the analogy, for the two measures differ greatly. The immunity conferred by vaccination is of indefinite duration and the operation itself when properly done is without danger; but the recently issued report of the British Army commission shows that the immunity following typhoid inoculation lasts for two or three years only, and furthermore there seems to be some foundation for the apprehension that typhoid inoculation may light up an incipient tuberculosis or weaken the natural resistance to that disease. These disadvantages ought not to count against the employment of the measure in an emergency, as in the case of hospital physicians and nurses or when large bodies of troops are in camp in a new country where strict sanitary rules cannot be enforced. A traveler going to countries where modern ideas of sanitation are ignored, might also be advised to submit to an inoculation.

The arguments against the universal practice of antityphoid vaccination are well put by Dr. Doty in an article in this issue of the Medical Record. The author speaks with the authority of a practical sanitarian, but possibly with the bias of one as well, for we think he would restrict a little too narrowly the use of antityphoid vaccination. In a hospital, for example, where there are many typhoid patients the risk of direct infection for the nurses is very great and absolute safety for them lies only in preventive inoculation. However, one need not accept all his arguments to be convinced of the unwisdom of the advocacy of a general typhoid inoculation, especially of children, in a community such as this, where there is every reason to expect that a continuance of the measures now in force will in time, in a short time, make the city practically typhoid free.

TRUE OZENA AND THE BACTERIUM PEREZ.

The difficulty in distinguishing between the various types of ozena and fetid rhinitis has always been caused by the absence of distinctive characteristics. For while bacterial life evidently is responsible for the various decompositions which give rise to the odors, the germs have commonly been regarded as saprophytes. Supposing that certain congenital and acquired deformities or diseases of the nose pave the way for the accumulation of crusts which decompose, any treatment which might prevent the crusting or even destroy the activity of the saprophytes could be regarded as curative. In the remote past attempts have been made to isolate a germ to be held responsible for the very beginning of ozena as an entity. And with the dawn of serotherapy it was sought to prepare antisera for this malady. Such efforts in the minds of some good judges have been formed on and pronounced a reproach to serotherapy. In the meantime Perez of Buenos Ayres has pursued the even tenor of a research based on the assumption that ozena is a specific disease. For twelve years he has labored continuously in this direction. He now claims that ozena is an infectious and transmissible disease, due to a germ styled by him *Coccobacillus fœtidus nasi*. This gives in culture the characteristic ozena odor. In order to make sure of the validity of his finds Perez carried out many researches in the Paltauf Institute for Serotherapy at Vienna.

At a meeting last June of the K. k. Gesellschaft der Aerzte zu Wien (*Berliner klinische Wochenschrift*, September 1), Hofer announces his work corroboratory of Perez's claims. Injection of a bacteriotoxin containing the bacterium into experiment animals caused an inflammation of the inferior turbinal bones, from the secretion of which the bacillus of Perez could be recovered. This experiment showed the remarkable rhinotropic action of the injection. The presence of the Perez bacillus in the blood could also be shown by agglutination tests. The inflammation of the lower turbinals leads clearly to atrophy, showing that ordinary atrophic rhinitis may be due to this microorganism.

Syphilis Hereditaria Tarda.

Late inherited syphilis is one of the rarer affections of childhood. Presenting mostly the same manifestations as tertiary syphilis at any stage of life, it suggests a number of important speculations. The question arises as to whether the condition is a strictly late syphilitic process, with a definite period of latency, or whether it is the gummatous stage of an already manifest syphilis of the infantile period. This subject is handled in an illuminating manner by George Alsberg in the opening article of the *Festschrift* dedicated to Adolf Baginsky, which constitutes Vols. 60 and 61 of the *Archiv für Kinderheilkunde*. Alsberg is inclined to question the existence of a syphilis hereditaria tarda, in view of the fact that cases of this condition usually show one or more of the characteristic manifestations of early syphilis, such as the rhagades about the mouth, and the lighter color and folded condition of the labial borders. The important studies of Hochsinger are cited in confirmation of this view. This observer alludes to the non-eruptive forms of congenital syphilis, and to the diagnostic significance of the rhagades about the mouth, and of cranial deformities. The more intense the infection the greater are the probabilities of relapses, and of the development of tertiary lesions, such as those of the bony system. The later the period of childhood the more do the cutaneous manifestations retire to the background, and the more prominent become lesions of the bones, hyperplasias of the lymphoid tissues, and nervous manifestations.

Vaccinola.

A distinction has not generally been made between primary and secondary vaccination, which latter includes auto- and heterovaccination. Yet in each case the germ has passed, perhaps through some subtle change. In the old days of arm-to-arm vaccination, whether immediate or delayed, this possibility was but little thought of. It was well known that inoculation variola was milder than epidemic variola, and that varioloid was milder than inoculation variola. Similar distinctions may well obtain between natural and artificial primary vaccina, generalized vaccina, and auto- and hetero-infection as regards human beings. At a recent session of the Medical Society of the Poliklinik at Nürnberg (*Muenchener medizinische Wochenschrift*, September 2) Kraus reports cases of auto- and heterovaccination under the designation vaccinola. A woman whose child had recently been vaccinated sustained an inoculation on both lids of one eye. The resulting lesions were so severe that a diagnosis without a history would have been most difficult. He also mentions the case of a child, who after vaccination, developed secondary lesions upon both lids of one eye.

News of the Week.

Health of the Canal Zone.—For the month of July, 1913, the annual average death rate from all causes among employees was 7.66 per thousand, representing a total of 37 deaths, of which 26 were due to disease and 11 to violence. This is the lowest rate on record for the month since 1904. The annual average death rate per thousand in the cities of Panama and Colon and the Canal Zone, including employees and civil population, was 24.86, which is 1 point higher than for the same month of last year. The chief causes of death were as follows: Dysentery, 2; lobar pneumonia, 5; malaria, 2; tuberculosis, 7; typhoid fever, 1. There were no cases of yellow fever, smallpox, or plague. The report includes a striking diagram showing the decline in the number of cases of malaria among employees during the first half of each year from 1906 to 1913. In 1906 the morbidity from malaria for the six months from January to July was 46.9 per cent.; in 1907, 25.6 per cent.; 1908, 11 per cent.; 1909, 12.5 per cent.; 1910, 10.5 per cent.; 1911, 12.7 per cent.; 1912, 6.6 per cent.; 1913, 4.5 per cent.

City Death Rate.—For the week ending September 20, the death rate in New York City was 13.20 per thousand, representing a total of 1,359 deaths, whereas for the corresponding week of 1912 the rate was only 11.72, and the total number of deaths 1,162. The increase was generally distributed; the

number of deaths from influenza, bronchitis, pneumonia, pulmonary tuberculosis, and heart and kidney diseases all being greater than last year.

The N. Y. State Board of Medical Examiners held their annual meeting in the Education Building at Albany, Wednesday, September 24. Dr. Henry B. Minton of Brooklyn was elected President; Dr. William H. Park of New York City was elected Vice-President. The Board adopted a new set of rules. Hereafter appeals for the review of rejected papers shall be in writing and shall be sent to the Secretary of the Board within thirty days after receiving notice of failure to pass; and between any examination in which a candidate fails, and a succeeding one which he takes, he must faithfully pursue his studies for at least six months longer and furnish satisfactory evidence thereof to the Board of Medical Examiners.

Cost of Sick Aliens.—The Commissioners of Accounts, who have been investigating the public hospitals of New York City, in a recent report to the Mayor state that the city spends $70,000 a year for the hospital treatment of indigent aliens admitted to this country only because of lax methods of physical examinations at Ellis Island. It is recommended that this expense be shifted to the Federal Government. The report states that during the last three years 9,879 aliens were treated at Bellevue and Allied Hospitals free of charge, and that the average cost for each patient was $21.10, making a total of $208,466.90 expended for this purpose during those years.

College of Physicians and Surgeons.—The 160th year of the College of Physicians and Surgeons, Columbia University, New York, was opened on September 24 with formal exercises in the College hall, at which Prof. George E. Brewer spoke on "Standards of Success in the Practice of Medicine." In all 317 students have been enrolled, the first year class numbering 100; the second, 68; the third, 80; the fourth, 64; and the special students, 5.

Typhoid Epidemic.—The epidemic of typhoid fever on the East Side of New York City has continued without much sign of abatement, and up to September 27 271 cases had been reported. Of these, Bellevue Hospital was caring for considerably more than a hundred, and Beth Israel Hospital for at least 25. At the former place it was said that the nursing force would need additions as the present staff was much overworked. Several deaths have occurred among the hospital patients.

Course in Sex Hygiene.—A new course in sex hygience for teachers has been arranged at the School of Pedagogy of New York University. Ten one-hour lectures will be given on alternate Saturdays, beginning on October 19, and the lecturers will be Dr. Edward L. Keyes, Jr., Dr. Rosalie Slaughter Morton, Dr. Thomas M. Balliet, and George W. Hunter. The aim of the course will be to give teachers a knowledge of the facts and principles constituting the matter of such instruction. The method of teaching will form the special topic of a similar course to be given next year, and will be treated only incidentally in the present course.

Bureau of Eugenics.—Dr. Joseph J. Craven of the Board of Health of Jersey City, N. J., has been assigned the task of organizing a Bureau of Eugenics for the board. It is planned to issue a pamphlet on the latest scientific methods of rearing children, which will be widely circulated among the mothers of the city.

Immigration Totals.—More immigrants arrived in the United States in the fiscal year ending June 30, 1913, than in any preceding year with one exception. The total number was 1,197,092, while during the year ending June 30, 1907, 1,285,349 aliens were received. In only five years since 1820 have more than a million immigrants reached this country. The 1913 total comprised 808,144 males and 389,748 females. Of those debarred 15,062 were males and 4,276 females. South Italy sent 231,613 immigrants during the year; Germany, 80,865; France, 20,052; England, 55,522; Ireland, 37,023; and Japan, 8,302.

Medical Milk Commissions and Certified Milk.—The first bulletin in the new departmental series of the United States Department of Agriculture is a contribution from the Bureau of Animal Industry entitled Medical Milk Commissions and Certified Milk and is a revision of a previous bulletin on the same subject. The bulletin describes the origin and meaning of "certified milk." The word "certified" has been registered in the United States Patent Office and may only be used by a duly organized medical milk commission. About 125 dairies are engaged in producing certified milk and the daily production is 25,000 gallons, an increase of 300 per cent. in five years. However, only about one-half of one per cent. of the total milk supply of the country is certified. The bulletin also describes the equipment and methods necessary for the production of certified milk and points out that expensive equipment is not a necessity so much as careful and unremitting attention to details. An appendix to the bulletin gives the standards for the production and distribution of certified milk as adopted by the American Association of American Milk Commissions at its 1912 meeting.

Milk Stations' Report.—The twenty-second year of the infant milk stations founded and maintained in New York by Mr. Nathan Straus was completed on September 26. From the eighteen depots in Manhattan the output during the year was 2,193,210 bottles of pasteurized milk, while 1,545,419 glasses of milk were served in the parks and on the recreation piers. During the entire twenty-two years 35,000,000 bottles of milk and 18,000,000 glasses have been supplied.

Personals.—Dr. Walter Mendelson of New York has been elected by the alumni of Columbia University to fill the vacancy caused by the death of Mr. J. Pierpont Morgan in the Board of Trustees of the University. The election will be confirmed by the trustees at their next meeting. Dr. Mendelson was graduated from the College of Physicians and Surgeons in 1879, and has for several years served as president of the Association of the Alumni of the College.

Dr. Hideyo Noguchi of the Rockefeller Institute, New York, on September 23 presented the results of his researches on the etiology of rabies before the German Congress for Nature Study in Vienna.

Dr. Walter Bensel retired on October 1 from the office of Sanitary Superintendent of the Board of Health, New York, after twenty-one years' service in the department. He was appointed sanitary superintendent on July 1, 1907.

Dr. Richard P. Strong and his party have returned to Boston after a four months' trip through Central America, Peru, and Ecuador, where material was collected for the new department of tropical medicine in the Harvard Medical School. Besides Prof. Strong the party comprised Prof. E. E. Tyzzer, Director of the Harvard Cancer Commission, Dr. Charles Brues, instructor in economic en-

tomology, and Dr. W. W. Sellards, instructor in medicine at Johns Hopkins University.

Dr. Lucius W. Hotchkiss of this city was severely injured in an automobile accident on the Morristown turnpike in New Jersey on Sunday last. He has been cared for at the Memorial Hospital in Montclair, and it is a pleasure to learn that it is expected he will be able to return to his home in a few days.

New York Neurological Society.—The next regular meeting of this Society will take place at the Academy of Medicine on Tuesday evening, October 7. Clinical cases will be presented by Drs. Karpas, Climenko, and others, and there will be a discussion on the intraspinous method for the treatment of metasyphilis (paresis) by Dr. W. Hough, Clinical Pathologist of the Government State Hospital for the Insane, Washington, D. C.; Dr. J. A. Fordyce, of New York; Dr. Henry Cotton, of Trenton State Hospital; Dr. Homer Swift, Dr. A. W. N. Ellis, and others.

Society of Sanitary and Moral Prophylaxis.—A regular meeting of this society will be held on Thursday evening, October 9, at the Academy of Medicine, at 8.30 o'clock. The paper of the evening, "Are Sanitary and Moral Prophylaxis Natural Allies?" will be read by Dr. Richard C. Cabot of Boston, Mass.

Safety Congress.—The Second Safety Congress of the National Council for Industrial Safety was opened at the Hotel McAlpin, New York, on September 23. Plans for the establishment of a Museum of Safety were discussed, and moving pictures portraying various street accidents were exhibited. These are to be used in the Chicago schools as an example of the right and wrong way of crossing streets, getting off and on of street cars, etc. The subjects for discussion during the congress include fire escapes and exits, organized safety, the Pennsylvania Department of Labor and Industry, and fire drills and fire protection.

Congress of Hydrology.—The IX International Congress of Hydrology, Climatology, and Geology will be held in Madrid, Spain, on October 15 to 22, 1913. Dr. Guy Hinsdale of Hot Springs, Va., has been appointed a member of the Central Committee, representing the United States.

Gifts to Charities.—By the will of the late Bernard Wolbarst of New York the sum of $1,000 is bequeathed to Beth Israel Hospital of this city.

By the will of the late Elizabeth Dorsey of Philadelphia, who died at Colorado Springs, Col., bequests are made as follows: $1,000 to the Woman's Hospital of Philadelphia, $500 to the Germantown Hospital, $2,000 to the Adirondack Cottage Sanitarium at Saranac Lake, N. Y., and $1,000 to the endowment fund of the Colorado Cottage.

The Massachusetts General Hospital of Boston receives $30,000, and the Boston Children's Hospital $25,000 by the will of the late Miss Harriet O. Cruft of that city.

By the will of the late Julia Garrett of Philadelphia bequests are made as follows: $50,000 to the Orthopedic Hospital and Infirmary for Nervous Diseases, to endow the William Evans Garrett Memorial Ward, $25,000 to the Pennsylvania Epileptic Hospital and Colony Farm at Oakbourne, $10,000 to the Bryn Mawr Hospital, as a memorial to William E. Garrett, Jr., and $10,000 to the Episcopal Hospital.

By the will of the late Fanny R. Dickson of Philadelphia the sum of $5,000 is bequeathed to the trustees of the University of Pennsylvania for the maintenance of a bed already established in the orthopedic department of the University Hospital.

By the will of the late Margaret H. Frederick of Philadelphia the sum of $5,000 is bequeathed to the Hahnemann Hospital and the sum of $250 to the Ladies' Aid Society of the Presbyterian Hospital.

By the will of the late Cornelius A. Lane of Philadelphia the sum of $5,000 is bequeathed to St. Vincent's Home and Maternity Hospital, $500 to St. Joseph's Hospital, $500 to St. Mary's Hospital, and $500 to St. Agnes' Hospital.

The American Public Health Association which met at Colorado Springs on September 9 elected the following officers: *President*, Dr. W. C. Woodward, Washington, D. C.; *Secretary*, Dr. Professor Solskar M. Gunn of the Massachusetts Institute of Technology, Boston, Mass.; *Treasurer*, Dr. Livingston Strand of New York; *Chairman* of the Sociological Section, Dr. Larence Vieller of New York; *Vice-Chairman*, Dr. Hoyt E. Dearholt of Minneapolis.

Medical Society of the State of Pennsylvania.—At the annual meeting just held at Philadelphia the following officers were elected for the ensuing year: *President*, Dr. E. B. Heckel, Pittsburgh; *First Vice-President*, Dr. H. D. Jump, Philadelphia; *Second Vice-President*, Dr. J. B. Amberson, Pittsburgh; *Third Vice-President*, Dr. J. H. Wilson, Philadelphia; *Fourth Vice-President*, Dr. J. H. B. Murray, Washington; *Secretary*, Dr. C. L. Stevens, Athens; *Assistant Secretary*, Dr. W. H. Cameron, Pittsburgh; *Treasurer*, Dr. G. W. Wagner, Johnstown; *Trustees for Three Years*, Dr. W. L. Estes, South Bethlehem; Dr. T. B. Appel, Lancaster, and Dr. H. W. Goss, Sunbury; *Delegates to the American Medical Association*, Dr. Adolph Koenig, Pittsburgh; Dr. J. M. Baldy, Philadelphia; Dr. A. R. Allen, Carlisle; Dr. L. B. Kline, Catawissa, and Dr. Herbert B. Gibbey, Wilkes-Barre.

Federation of State Medical Boards.—At the Executive Committee meeting of the Federation of State Medical Boards of the United States held at the Hotel Manhattan, September 2, 1913, Dr. James A. Duncan, formerly of the Ohio Board, Dr. Albert de Bey, formerly of Iowa Board, and Dr. Charles A. Tisdale, formerly of the California Board, were nominated for Honorary Fellowship in the Federation. The next annual session of the Federation was called for Wednesday, February 25, 1914, at Chicago, Ill.

Abington (Pa.) Hospital.—As a memorial to his wife, the late Stella M. Elkins, Mr. George W. Elkins of Ogontz, Pa., has agreed to assume the entire obligation of erecting a new hospital at Abington, Pa., the cornerstone of which was laid on September 25. The sum of $30,000 has already been collected, and this will be used as the nucleus of an endowment fund. Mr. Elkins' gift will amount to about $100,000. The hospital will be built of red brick, with marble trimmings, and it will be 107 x 100 feet in size, with a capacity of 60 beds.

Obituary Notes.—Dr. Roland D. Jones of New York, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1881, died suddenly while in his automobile, on September 25, from heart disease, aged 57 years.

Dr. T. H. Frey of Beaumont, Tex., a graduate of the Memphis Medical College in 1884, died September 6, aged 48 years.

Dr. L. W. Smith of Sacul, Texas, was found

dead in his room in a hotel in Houston, Texas, on September 10.

Dr. Charles E. Campbell of New York City, a graduate of the New York Homeopathic Medical College in 1894, died after an operation at his summer home on Block Island on September 12, aged 72 years.

Dr. Charles John Martin Willich of Brooklyn, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1893, died at his home from cancer of the throat, on September 23, aged 61 years.

Dr. Albert Thornton Birdsall of Brooklyn, N. Y., a graduate of the University of Minnesota, College of Medicine and Surgery, Minneapolis, in 1896, instructor in surgery at the New York Post-Graduate Hospital, consulting surgeon at the Brooklyn Tuberculosis Clinic, and a member of the New York State and Kings County Medical Society, the Brooklyn Pathological Society, and the Association of Tuberculosis Clinics, died at his home from pneumonia, on September 24, aged 43 years.

Dr. Joshua W. Hering of Westminster, Md., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1855, a member of the Maryland State and Carroll County Medical Societies, and until recently a member of the State Public Service Commission, died at his home on September 23, aged 80 years.

Dr. Orren Burnham Sanders of Boston, Mass., a graduate of the Boston University School of Medicine in 1879 and a member of the New England Branch of the American Urological Society and the Massachusetts State and Suffolk County Medical Societies, died at his home on September 25 from injuries received in an automobile accident at Quincy a few days before.

Dr. William Johnston Beattie of Littleton, N. H., a graduate of the Bellevue Hospital Medical College, New York, in 1889, president of the Littleton Hospital, and a member of the New Hampshire State and Grafton County Medical Societies, was struck by a passing automobile in the street near his home and instantly killed, on September 26, at the age of 48 years.

Obituary.

REGINALD HEBER FITZ, M.D., LL.D.

BOSTON.

Dr. Reginald H. Fitz, whose death following an operation on the stomach occurred on Tuesday of this week, was born in Chelsea, May 5, 1843. He was a graduate of Harvard in both arts and medicine, receiving his A.B. in 1864 and M.D. in 1868. His Alma Mater conferred upon him the honorary degree of LL.D. in 1905. He began his teaching relations with the Harvard Medical School in 1870 when he was appointed instructor in pathological anatomy; in 1873 he became assistant professor, and in 1878 full professor of pathology; in 1892 he was appointed Hersey professor of the theory and practice of physic, and retired in 1908 when he was made emeritus professor. Dr. Fitz was an original thinker and made many valuable contributions to medical science, his work on appendicitis and on the pathology of the pancreas being especially noteworthy. He was joint author with Dr. H. C. Wood of a treatise on "The Practice of Medicine," published in 1897.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRITISH ASSOCIATION—SIR OLIVER LODGE'S PRESIDENTIAL ADDRESS—EPIDEMIC IN A CHILDREN'S WARD TRACED TO A DUST HEAP—TOWN DUST PROBLEM—SANITARY INSPECTORS' CONFERENCE—SIR J. CRICHTON-BROWNE'S PRESIDENTIAL ADDRESS—A DOCTOR ACCUSED OF CRUELTY—A CHRISTIAN SCIENCE VICTIM.

London, September 12, 1913

The eighty-third annual meeting of the British Association, our chief scientific organization, is being held. It was opened on Wednesday at Birmingham, and correspondents say that so far it is a very successful meeting. The presidential address, which we look forward to usually as the most important utterance, was delivered by Sir Oliver Lodge. As might be expected from so eminent a physicist, it consisted of a mixture of physics and metaphysics. The first part was concerned with the problems of continuity and discontinuity. The president declared himself an upholder of ultimate continuity and a firm believer in the ether of space, for although the present generation has been educated into that idea, there has been in late years a tendency toward reviving the other doctrine. Matter has long been atomic in the same sense that anthropology is atomic. The unit of matter is the atom as the unit of humanity is the individual. Both can be counted, as can the sands on the shore or the hairs of the head. The only difficulty is they are so numerous. So are the atoms in a drop of water, they outnumber the drops of an ocean, and in the briefest time of stating their number, fifty millions or so may have evaporated. All things with natural units can be counted. To apply number to a continuum you must first cut it up into artificial units. Biology has long had units, cells nuclei, and some discontinuity in boundaries and cell walls.

The study of the ether belongs to physics alone and is the largest fundamental ingredient in the cosmos. "Matter it is not," said Sir Oliver, "but material it is." It is the great engine of continuity, and it may be more, for without it there could hardly be a material universe at all. Some critics called him a vitalist—a term he never used. In a sense he was—but not if it meant an appeal to a vital force against the laws of chemistry and physics. Those laws must be supplemented but by no means superseded. In science there was no appeal to occult qualities. To say a thing was an act of God and say no more left it unexplained. As an ultimate statement it might be not only true but universal in its application. But there were always proximate explanations which might be looked for and with patience be found, as lightning, earthquakes, and other things had been reduced to natural causes. No ultimate explanation was ever attained by science. Before all the actions of living things could be explained some causes not yet admitted must be postulated. A live thing obeyed the laws of physics, like everything else, but it initiated processes and produced results which could not have occurred without it—from a bird's nest to a honeycomb, from a deal box to a warship.

There was plenty of chemistry and physics about a vital action, but for a complete understanding of it something beyond was needed. He would risk the assertion that Life introduced something incal-

culable and purposeful amid the laws of physics—so supplementing them, otherwise leaving them as they were. Scientists were rightly hostile to superstition, but possibly that word was occasionally wrongly applied. To a superficial observer a scientific act might seem superstitious. To combat malaria Sir Ronald Ross did not erect an altar; no, he oiled a pond as a libation to the genii. What could be more ludicrous? It was not reasonable to say a thing eluded investigation because we did not knock up against it. The ether made no appeal to our senses so some began to deny its existence. Our organs of sense are adapted to the observation of matter and nothing else appeals directly to us. So there could be no terrestrial manifestation of life without matter. Hence some said they discerned in matter the promise and potency of life. Naturally enough of all terrestrial manifestations. How else could it manifests itself? Materialism was appropriate to the material world but everything beyond belonged to another region and could not be explained in terms of physics or chemistry and so some denied its existence, but such philosophizing was unjustifiable and really bad metaphysics. Going further, the president, summarizing the result on his own mind of thirty years' experience of psychical research, begun without predilection—indeed with the usual hostile prejudice he stated the conviction of himself and coworkers that occurrences now regarded as occult can be examined and reduced to order by methods of science carefully and persistently applied and that already facts so examined have convinced him that memory and affection are not limited to that association with matter by which they can alone manifest themselves here and now, and that personality persists beyond bodily death. Discarnate intelligence, under certain conditions, may interact with us on the material side, thus indirectly coming within scientific ken; we may gradually attain some understanding of a larger, perhaps ethereal existence, and of the conditions regulating intercourse across the chasm. The universe is larger than we have any conception of and no one method of search can exhaust its treasures. Genuine religion has its roots deep down in the heart of humanity and in the reality of things. It is not surprising that our methods do not grasp it; the actions of the Deity make no appeal to any special sense, only a universal appeal, and our methods are incompetent to detect complete uniformity. We are deaf and blind therefore to the grandeur around us unless we have insight enough to appreciate the whole—to recognize in the fabric of existence, flowing steadily from the loom in an infinite progress towards perfection, the ever-growing garment of a transcendent God.

An outbreak of typhoid fever in the children's ward of the Southwark Infirmary was at first a puzzle to the medical superintendent. But his suspisions fell on a dust heap which was established close by. How long it has been there seems to be unknown, but according to credible testimony a long time, and it belongs to the Camberwell Borough Council, though by what right does not appear. Howbeit the medical superintendent believes the epidemic is due to emanations from this heap and the wonder is that it should so long have been tolerated in the district—and above all close to the infirmary. On September 1 twenty-eight cases with six deaths were reported. By the 8th the figures had increased to thirty-four and eight.

This outbreak has stirred the apathy of Londoners who are accustomed to pride themselves on their sanitary arrangements and are now asking how the county council could have tolerated the presence of such a source of infection or what the Medical Officer of Health was about to overlook it. Of course it is a common axiom that in all cities the disposal of the refuse from the streets, houses, shops, and other premises is one of the most difficult problems for the authorities. In London the bulk of the accumulations to be dealt with is so enormous that notwithstanding all efforts to utilize some of it a great expense is incurred in removing the waste, said to be over a million tons in weight a year. About half, for the most part from the streets, is sent into the country to which may probably be added most of that disposed of by contract—some 100,000 tons. Many have supposed that the remainder was disposed of by the destructors of which much has been heard; but the last returns only give about 370,000 tons dealt with in that way, while 320,000 were sent away in barges and 180,000 by rail. Sifting was applied to 43,000 tons and the process resulted in 487 tons that could be used in the foundations of streets. There remain 46,000 tons disposed of in shoots—but where these may be located does not appear. It is to be hoped none of them are in such dangerous positions as that chosen by the Camberwell Borough Council. A very curious circumstance is the remarkable difference in the cost of getting rid of the refuse in different localities—a difference ranging between 6 shillings and 10 pence per ton.

The Local Government Board is being subjected to much indiscriminate criticism in this matter but its powers are not so extensive as is commonly supposed. It can call the attention of the boroughs to such nuisances but cannot enforce its views upon them. Twenty years ago Dr. Parsons investigated for that Board the whole subject of refuse disposal and in his report one of the suggestions was that the Local Government Board might be entrusted by Parliament with compulsory powers in this direction. This and other suggestions in that report seem to have been neglected. But it is only right to add that the boroughs have always been ready to give full consideration to any communication from the Local Government Board.

On Tuesday Sir J. Crichton-Browne delivered the Presidential address at the conference of the Sanitary Inspectors' Association. The dust problem furnished him with a timely text of which he made the most. After mentioning the infinitesimal atmospheric natural dust to which we owe the blueness of the sky, clouds of all kinds, he said it is not to this we trace disease but to the dust produced by human agency. Our modern civilization he described as one vast grind, attrition being almost synonymous with progress. The dusts generated are responsible for no little sickness and death in spite of great improvements in ventilation of factories and workshops. Turning to municipal or town dust he said it was most to be feared as a carrier of pathogenic germs and microbes of many kinds which can resist drying and may be wafted about with the particles. So catarrh, influenza, hay fever, etc., may be disseminated. Tuberculosis, too, is similarly spread in the dust of the dried sputum. In all dust the danger of implantation of germs, fresh or dried, is enhanced if associated with corrosive, chemical, or mechanically wounding elements. Sharp particles of mineral matter may plow up a way in the tissues through which pathogenic germs

may enter. Even tetanus might be caused by road dust carrying it to some superficial wound, for the organism lives in the alimentary canal of the horse and so is found in the manure of street refuse as well as in the soil of gardens and other places. The antitoxin is efficacious if used immediately and in these days of dust-scattering motors the president suggested that a tube of antitoxin might well form part of the furniture of a car so that in case of accident it might instantly be applied to any dust-impregnated wound in which tetanus germs might be present.

A doctor who took invalids into his house has been tried on a charge of cruelty to one who was said to be insane but was by some practitioners declared not to be certifiable. Discharged nurses gave evidence that the defendant had beaten a patient—a young girl—with a slipper and he admitted he had given her two slaps. Much evidence on both sides was offered and there seems to have been great excitement over the trial; for on the jury declaring the Crown had not proved the case there was loud cheering—so much that the judge ordered the court to be cleared and pronounced the scene disgraceful. When the doctor, who was thereupon discharged, left the court he was seized by a number of young men and carried shoulder-high as they sang "he's a jolly good fellow."

A man has been charged with manslaughter for causing the death of his daughter, aged 7, by not procuring medical aid. His defence was that he left the case to a Christian Science woman. The judge ruled that to convict the neglect must be wilful to be an offence. If the man knew the child was dying of diphtheria he deserved punishment—scientist or not. If he were too stupid to see she was dangerously ill they did not convict of criminality for pure stupidity. The jury found him not guilty and the judge advised him for the future when he was in doubt to send for a doctor.

1. The Workmen's Compensation Act from the Legal Standpoint. J. C. Johnston.
2. The Workmen's Compensation Act as Viewed by a Member of the Industrial Accident Board. D. M. Holman.
3. The Workmen's Compensation Act as It Affects the Physician. R. M. Merrick.
4. Notes of the First Annual Conference on the Medical and Social Work of the Psychopathic Hospital, Boston, Mass. W. Channing, H. H. Baker, G. E. Eversole, V. V. Anderson, Mary C. Jarrett, W. P. Lucas, A. W. Stearns, D. Gregg, H. M. Adler, B. H. Ragle, J. G. Blake, A. Myerson and E. E. Southard.

1. **The Workmen's Compensation Act of Massachusetts.**—J. C. Johnston discusses certain aspects of this act. He states that this and similar laws are an embodiment of the social trend of modern times as well as a clear expression of the social interest in the individual. In considering the operation and effect of a workmen's compensation act there are two factors which may be considered permanent and which must necessarily control its development. There will be constant economic pressure to lower the cost of insurance, which the community has ultimately to bear in the increased charges for the products of labor. Inasmuch as the act is designed primarily to protect the workman there will be a constant effort to secure for him the largest possible share of the premiums that are collected from the public. The continual interplay of these two forces will tend necessarily to reduce to a minimum the cost of operation, in which one must include charges for medical and hospital service. The report of the Wisconsin Employer's Mutual Liability Insurance Company shows during the year 1912 the payment of $9,588.81 for compensation and $16,385.87 for medical and surgical aid, including hospital care, or, in other words, out of $45,974.68 disbursed, the doctors have received 35 per cent. plus of the total amount. The report of the Massachusetts Employers' Mutual Insurance Company, covering six months' experience under the Massachusetts Act, shows expenditures of $11,413.72 for medical and hospital services, with unpaid estimated liabilities on this account of $26,527.98, as compared with a total of $48,734.51 paid or payable on account of benefits. In other words, the cost of medical service was slightly more than three-fourths of the amounts received in benefits by the workingman. To put it in another way, the doctors have received 43 per cent. plus of a total of $86,674.21.

2. **The Workmen's Compensation Act of Massachusetts.**—D. M. Holman states that this law is elective both for employer and for employees. An employer can choose to come in under the act or to stay out. If he elects to give his workmen the benefit of the act he takes out an insurance policy. If he chooses not to come in under the act he does nothing, but if an employee of his is injured the employer stands liable in heavy damages, the sole requirement being that the injured workman prove negligence on the part of his employer, superintendent, or agent, or defect in the ways and machinery. His three main defenses are stripped from him. An employee can also exercise his choice to come in and rely on the Workmen's Compensation Act or stay out and claim his common law rights, but if he pursues the latter course he must prove that he was in the exercise of due care, that the accident did not arise out of the negligence of a fellow workman, and that he had not assumed the risk.

1. **Preoperative Caution.**—H. A. Wilson emphasizes the dangers and uncertainties of the immediate and remote results of operations. Evidence is accumulating that operations are not always approached with careful preliminary study. As a matter of fact, the whole responsibility for careful preoperative diagnosis should not be thrown upon the surgeon. The internist should assume his proper place before and after operation. He should take part in the preparation of the patient, and in determining the latter's ability to withstand the shock of the operative procedure; he should occupy a prominent position in judging of the diagnostic significance of the various laboratory reports; and he should be in close association with the surgeon after the operation. The prevailing custom in the better hospitals of having numerous consultations of surgeons with internists and specialists, together with elaborate laboratory studies, must inevitably result in safeguarding the best interests of the patients. George W. Guthrie is quoted to the effect that seventy-five per cent. of the patients that formerly went to the Mayo brothers, expecting to be operated upon, were sent away without operation. This is because these surgeons often find, by means of an elaborate system of preliminary study, at the hands of numerous skilled investigators, that there are often better ways of curing

the patient than by operation. The physician should not be too hasty in subjecting a patient to the surgical procedure and yet should discriminate in the avoidance of fatal postponement. When an operation is finally decided upon he should take pains to assure himself of the ability of the surgeon whom he recommends; because, when he suggests and cooperates with a surgeon he thereby tacitly assumes proportionate responsibility for the results.

2. **The Position of the Stomach in Children.**—J. W. Sever finds as the result of the study of eighty-three cases of averagely developed children that the average position of the stomach is a much lower one than has been previously suspected, and that to find a stomach at or well below the crests of the ilium is not at all unusual. Only one of these children had symptoms which were due to a dilated colon, which condition caused chronic constipation, and not to a stomach which showed a moderate ptosis. The children were otherwise perfectly well as far as their digestive apparatus was concerned. The author believes that ideas as to the shape of the child's stomach should be changed. In his series it was generally large and either horizontal or of the sink drain type. The ideal so-called cow's horn stomach was rare. He does not believe that posture in children, apart from the erect position of human beings in general, has nearly as much to do with ptosis as has formerly been believed. The child's stomach is lower than is generally supposed, and to find a stomach low in a child does not, therefore, mean that there is a pathological ptosis. Poor posture should be corrected and impaired general health built up, but neither is a cause of ptosis in children, nor is a low stomach necessarily a weak link in the chain of a child's development.

3. **The Climate of San Diego, Cal., with Relation to Renal Diseases.**—By P. M. Carrington. (See MEDICAL RECORD, August 2, 1913, page 227.)

5. **The Uses of Paraffin in Ozena.**—J. Auerbach presents a paper on the study of thirty-two cases of genuine ozena. His primary object was to note the effect of paraffin injected subcutaneously or subperichondrially into the nasal chambers; such injections have been done by European workers, who have reported brilliant results from their use. The author concludes from his experience that in the injection of hard paraffin of high melting point the danger of embolism is eliminated. The results so far obtained even in severe cases afford encouragement for the further use of paraffin injections in ozena. It is impossible to speak of a "cure," even in those cases which show a disappearance of the disagreeable symptoms. There is no influence anatomically on the atrophied structures. Functionally the results are all that can be desired, though all cases eventually require reinjection.

7. **Retropharyngeal Abscess.**—W. C. Billings and G. Wilson report an unusual case of this condition in an adult, which case illustrates the following three points: (1) The signs of retropharyngeal abscess may quickly disappear, the pus being dissipated in the loose fascia, and finding its way to some point distant from the original seat of fluctuation within the course of a few hours. (2) Immediate evacuation is necessary the moment the diagnosis is made, as a few hours' delay may make such a change in the picture that the diagnosis becomes doubtful. (3) The extreme gravity of the condition and the danger of complications should be borne in mind. Besides these three main points there are other minor points that are worthy of note. Chief of these is the fact that infection in the authors' case was from a sore throat that was in all probability due to syphilis. Owing to the failure of the Wassermann reaction and the inability to get a good history through lack of interpreters, this point could not be definitely decided, yet the probabilities remained in favor of syphilis. Another point which has been often emphasized before is that retropharyngeal abscess is especially liable to be complicated with pneumonia. Finally, the case will serve to emphasize the fact that the disease is not confined to childhood, and that owing to the anatomical arrangement of the parts it is especially liable to give rise to the most serious consequences. The arrangement of the muscles, fascia, and the lymph glands of this region is such that one may have infection occurring in any one of the following manners: (1) Infection from the middle ear, via the canal for the tensor tympani muscle. (2) Sphenoidal sinus infection. (3) Necrosis of the cervical vertebræ. (4) Direct injury to the pharynx itself. (5) Extension from lymphatic gland involvement; the lymph-nodes lying between the anterior surface of the vertebral column and the pharyngeal aponeurosis being especially liable to involvement. (6) Thrombosis or embolism arising in connection with septic processes.

3. **Roentgenoscopy of the Liver and Biliary Passages.**—By J. T. Case. (See MEDICAL RECORD, July 5, 1913, page 38.)

4. **Roentgenography of the Normal Kidney.**—S. B. Childs and W. N. Spitzer conclude from their study of this subject that pyelography is not only justifiable, but also necessary; however, none but the trained urologist should attempt it. Unless the lower border of the pelvis is concave the authors consider it abnormal. A pelvic content of over 15 c.c. should be viewed with suspicion and investigated further before its normality is accepted. Movement of the kidney of from 1 to 3.5 cm. over and above the physiological (respiratory) movement is normal. The ureteral catheter as a rule enters the upper oblique calyx and follows the roof of the kidney pelvis to do so, in a normal case. Angulations, curves, and kinks of the ureter are found in normal persons. Stereoscopic plates are not only necessary, but imperative, to demonstrate intrapelvic and extrapelvic conditions, and the course and kinks of the ureter. Length of ureter can be calculated only from the plate, and is of importance. Pain, shock, and subsequent rise of temperature are caused by rapid distention of the kidney pelvis rather than by any particular drug or percentage of drug that is used, and are unavoidable, if one properly fills the pelvis for diagnosis, although none of these disagreeable

sequelæ need be produced to an extreme degree or cause much disturbance, and can be obviated to a great degree. As the shape of the ureter is due to its laxity or tenseness, either of which conditions may be normal, and as its caliber varies considerably in normal subjects, and as it is still further altered by peristalsis, care should be exercised in drawing conclusions that pathological conditions exist because of apparent abnormalities of shape and course, or because of curves, kinks, and angulations, or apparent constrictions.

5. **External Bone Clamp versus Internal Bone Plate.**—By L. Freeman. (See MEDICAL RECORD, July 5, 1913, page 36.)

6. **Refrigerator Problems.**—J. R. Williams presents a series of data from which he draws the following conclusions: (1) The temperatures of cellars or living rooms in dwelling houses are not sufficiently low during the warm months of the year to protect milk and other perishable foods from rapid bacterial decomposition. Therefore, an efficient refrigerator in the home is a necessity. (2) Most of the refrigerators in common use are almost worthless and grossly uneconomical. (3) There is a large field for the manufacturer who will make a properly insulated and efficient box which can be sold at a moderate price. (4) If more economical methods of ice manufacture and distribution were employed, the cost of ice to the consumer could be materially lowered. (5) If to this saving were added that which would result from proper ice-box construction, refrigeration vastly superior to that now found in the average home could be had for at least one-fourth the present cost.

7. **Essential Hematuria.**—W. F. Braasch defines essential hematuria as a type unexplained by any of the definitely established renal conditions causing hemorrhagic urine. He presents an analysis of the cases observed at the Mayo clinic up to June 1, 1913, for which no clinical evidence of renal insufficiency, organic change of the renal parenchyma, or of renal infection was observed. Twenty-six of the patients in which this clinical diagnosis was made were operated on and fifty-one were not operated on. Three-quarters of the patients were males, which proportion accords with the general incidence of renal infection, and only sixteen of the seventy-seven were under forty years of age. Pain was severe in only five cases and then was evidently due to blood clots clogging the ureter. In 61 per cent. of the cases operated upon the duration of symptoms was over a year, in 8 per cent. over five years, and in 19 per cent. fifteen years or more. In the cases not operated upon the hematuria was of shorter duration. Evidence of central nervous lesion or marked neurosis was absent in all. The roentgenographs showed nothing abnormal. The surgical results were fairly brilliant. Eight patients reported recovery following a nephrotomy operation. Nephrotomy is not regarded as a certain method of cure, but nephrectomy gave comparatively excellent results; fourteen of the sixteen cases reported themselves in excellent health more than two years after operation. It would seem advisable as a rule to treat essential hematuria conservatively and exhaust every means of diagnosis before exploration is undertaken. This is justifiable, however, when one or two spells of hematuria have occurred, and is indicated if the patient has become incapacitated or a neoplasm is suspected. The author's experience does not support the nephritic etiology of the condition. Whatever the cause may be, hematuria apparently does not tend to shorten life, at least to any great extent. An occasional moderate hematuria without other symptoms should not necessarily require any active treatment.

9. **Public Health Aspects of Leprosy in the United States.**—By R. Blue. (See MEDICAL RECORD, July 5, 1913, page 43.)

10. **Clinical Aspects of Leprosy.**—By E Boeckmann. (See MEDICAL RECORD, July 5, 1913, page 43.)

11. **Dermatological Aspects of Leprosy.**—By I. Dyer. (See MEDICAL RECORD, July 5, 1913, page 43.)

12. **Morbidity Reports.**—J. W. Trask notes that the present purpose of morbidity reports is: (1) To show the occurrence of cases of infectious diseases which may be foci of spread; (2) to show the occurrence, distribution, and spread of certain diseases, more or less unknown, because of the possible value of this information; (3) to ascertain the cause or means of spread, as in pellagra and cancer; (4) to make proper treatment possible and prevent disease; and (5) to show the existence and location of conditions capable of causing illness or injury, as in the industrial diseases. He gives an account of the morbidity reports in England and Russia. These reports appear to be thoroughly carried out. He reviews the legislation in this regard in the different States, and gives a list of the notifiable diseases and the States in which they are notifiable by law. Smallpox is notifiable in forty-four States, diphtheria in forty, and scarlet fever in thirty-nine. Of the less commonly notifiable diseases cancer is notifiable in New York, and Chagres fever in Alabama. Venereal diseases are notifiable in California, Utah, and Vermont, but the name of the patient need not be given, and syphilis is notifiable in Porto Rico. Cases of mental deficiency, including epilepsy, are notifiable in New Jersey. Eight States have enacted laws requiring the notification of occupational diseases. The completeness of the reports in different States and cities may be estimated with some degree of accuracy by comparing the number of cases reported with the number of deaths due to the same cause, bearing in mind, however, that one's knowledge is still somewhat imperfect as to the fatality rate of certain of these disorders.

9. Suggested International Test for Disinfectants. S. Rideal.

1. **Continuity.**—Sir Oliver Lodge believes that occurrences now regarded as occult can be examined and reduced to order by the methods of science carefully and persistently applied, and that already the facts so examined have convinced him that memory and affection are not limited to that association with matter by which alone they can manifest themselves here and now, and that personality persists beyond bodily death. The evidence to the author's mind goes to prove that discarnate intelligence, under certain conditions, may interact with the individual on the material side, thus indirectly coming within his scientific ken; and that gradually one may hope to attain some understanding of the nature of a larger, perhaps ethereal, existence, and of the conditions regulating intercourse across the chasm. A body of responsible investigators has even now landed on the treacherous but promising shores of a new continent.

3. **Treatment of Brain Tumor.**—C. A. Ballance details the method of choice to be followed with rare exceptions in an infiltrating tumor of the brain. There is no doubt in his mind that decompression, not excision, is the right course to adopt. Decompression relieves the symptoms which depend on increased intracranial pressure.

The patient is not, as a rule, *in extremis* from the local effects of the tumor, but from the acute syndrome which supervenes, and is made comfortable and safe by a decompressive operation. By a decompression the author means a large craniectomy, best made over the site of tumor. An osteoplastic flap is a mistake. A cranial defect is essential; a cerebral protrusion, as Cushing says, is desirable. The cranial defect must be large and the dura must be opened, otherwise the intracranial pressure will not be relieved. Occasionally when a glioma is of small size and is situated at one pole of the brain the surgeon may be tempted to remove it. The results are the same as in tumors of other parts of the body. Recurrence and nonrecurrence seem to baffle prognosis. When operating for cancer, say of the breast or tongue, the surgeon may in the one case have the best reasons to hope for a cure, in the other he may anticipate an early recurrence. In each case he may be wrong; where all seemed well the growth may recur early and kill the patient, while the case which seemed discouraging may prove a great success. So it is in those rare instances in which a malignant growth in the brain can be apparently completely removed.

4. **Rupture of the Spleen; Splenectomy; Recovery.**—R. Seheult reports a case of traumatic rupture of the spleen in a boy aged thirteen years. In spite of the extent and gravity of the lesion there was an absence of urgent symptoms even after the lapse of forty-eight hours. It is remarkable that death did not ensue from hemorrhage, considering the fact that the patient was removed from place to place over a considerable distance before his admission to hospital. The condition of the pulse —viz., its irregularity, sudden variations, and slowness at various times—was an interesting feature in this case. The absence of postoperative sequelæ reported in other cases is also noteworthy. On looking up the literature at his disposal the author finds it is stated that removal of the spleen was practised for the first time by Zuccarelli (Saccharelli) in 1554; if so, it would appear that the operation fell at once into disfavor, for there is no record of its repetition until more than three centuries later, when Péan, of Paris, successfully extirpated a cystic spleen in 1867. Since that time the operation has been performed for various conditions and has become a well-established surgical procedure. Up to a few years ago, however, the mortality rate was high; in 1887 it seemed to have been as high as 73 per cent.; Cecil in 1894 estimated it at 51.6 per cent. Since that date there have been decided improvements in the results, due largely to the abandonment of the operation for splenic leucemia and other unfavorable conditions which proved almost invariably fatal. In 1906 B. B. Davis was able to place the mortality at 18 per cent. As regards the removal of the spleen for rupture Reigner recorded in 1893 the first successful case. In 1902 Berger had collected from the literature 69 cases of this nature, with 29 deaths—a mortality of 42 per cent. In 1906 Horz had obtained the reports of 35 additional cases, with a mortality of 29 per cent. Splenectomy consecutive to wounds of the organ has, therefore, been attended with a fair measure of success; in any case, it is beyond doubt the most rational and hopeful treatment, especially when it is borne in mind that the mortality in the unoperated cases has been computed to be more than twice that of the cases in which splenectomy has been performed.

7. **Lenticular Degeneration and Cirrhosis of the Liver.**—A. T. Henrici reports a case of this condition which was first described recently by Kinnier Wilson. The association of cirrhosis of the liver with degeneration of the nucleus lentiformis in this disease is so constant as to leave no doubt in the author's mind that there is an important relationship between them. Concerning this relationship two hypotheses present themselves: first, that the same substance which produces the liver changes also affects the lenticular nucleus; and second, that there is elaborated in the diseased liver some toxic body which has a peculiar affinity for the tissues of the corpus striatum. In the author's case there was a marked history of alcoholism, and the liver definitely showed an early stage of Laennec's cirrhosis. If it be granted that the lesions of the lenticular nuclei as here described are an early stage of the process described by Wilson, it would appear that the disease may be associated with other types of cirrhosis having a more definite etiology.

1. Mind and Motive: Some Notes on Criminal Lunacy. D. Nicolson.
2. Malingering. Sir John Collie.
3. Report on Urinary Antiseptics. A. Jordan.

3. **Urinary Antiseptics.**—A. Jordan concludes from his researches that the acidity of the urine is readily increased to an extent of more than double the normal by acid sodium phosphate, and to a considerably less extent by benzoates. With large doses of citrates it is easily rendered alkaline. Putrefaction of the urine and the growth of the staphylococcus is aided by alkalinity and delayed by acidity in proportion to the amount thereof. The reverse is the case with *B. coli*, but only to a small extent; its growth in both acid and alkaline urines is quite luxuriant. Hexamethylenetetramine is not itself antiseptic, but acts by producing formaldehyde in the urine. This only takes place in acid urine, and the drug is inert in alkaline urine. The degree of antiseptic power is proportionate to the acidity, and where this is normal or lighter the drug is far the most efficient of all the urinary antiseptics. Sandalwood oil is a bad general antiseptic, but appears to have a specific action on the staphylococcus which may apply to cocci generally. It is of some use in alkaline urine. Benzoic and salicylic acids are very similar in action. Both are fairly efficient antiseptics in the urine, but are of very little use in alkaline urine. Boric acid is an efficient antiseptic. Its action is unaffected by alkalinity, so that it is the most efficient drug in alkaline urine. Uva ursi is quite a good antiseptic. Its action is certainly not due chiefly to the arbutin it contains. The following are legitimate practical deductions: The use of urotropin (together with acid sodium phosphate, which should always be given with it) as a prophylactic before any operation or procedure where the urine may become infected is of the utmost value, since if the urine is clean and highly acid, and sufficient urotropin is given in small doses to keep it continually present, the urine will not support the life of any organism, and becomes indeed a powerfully antiseptic fluid. Urotropin should only be given where the urine is or can be made acid, otherwise it is inert. It should never be given with potassium citrate in *B. coli* infections. If it is desired to try the effect of making the urine alkaline in these conditions one should use boric acid and uva ursi infusion.

Pathological Phenomena in Fossil Animals.—Hennig insists upon the great importance of paleontological pathology, which is at present hardly recognized as a science, and we can deal only with the special case. Of special significance is the part played by abnormal conditions in the variation of species. Abnormities are in human anatomy not necessarily pathological. Virchow would never admit that the skulls of prehistoric men were anything but the vestigies of ordinary idiot brains. Here we see pathology invoked to explain variation. The cave bear ap-

peared to have been subject to arthritis deformans and it seems a fair inference that the Neanderthal man, his contemporary, shared the same affection. The most likely origin for the latter is the cold, dark, and damp cave life. Some cave bears have shown the most destructive and varied lesions of bone and cartilages which affected most of the osseous framework. The bones of the giant saurians showed similar alterations. Anomalies of horns are so common as to be regarded as nonpathological. A favorite subject of fossil pathology is the mammoth, for aside from the vast number of preserved skeletons, no less than twenty-two mummies have been preserved. All fossil and modern elephants are said to exhibit a dental anomaly known as tortuous molars. Caries of the teeth was practically nonexistent in fossil animals, until we reach the fishes. A group known as the pyknodons seems to have been subject to some affection in causing exposed pulp cavities, with lodgement therein of food particles. This bears a resemblance to human caries. While any masticating animal can wear its teeth down to the pulp cavities, there is no suggestion of caries. It is, however, true that while aboriginal man and the latest mammals are practically exempt from caries, exceptions are sometimes present, enough to suggest that modern caries among white men is a gradual evolution of the same state in savages, fossil men, and animals. In time we shall have a science of evolutionary pathology.

Spinalgia.—This term is used by Zuelzer in connection with the neuralgias. His paper he terms an entirely practical one; to include theoretical and fundamental considerations would be to include a great variety of subjects. Thus in Bechterew's disease or spondylitis rhizomelie, we see associated common neuralgias. From the same point visceral and other neuralgias are set up by adhesions in the anterior aspect of the vertebral column. Congestions in the spinal meninges cause radiating neuralgic pains, as seen, for example, in bronchial tuberculosis. The pains caused by certain visceral affections, as aneurysms, tumors, etc., also come under the head of spinalgia. To indicate three types of spinal neuralgia which often lead to confusion in diagnosis, we may cite bronchial gland tuberculosis, "insufficiency" of the vertebræ, and acute rheumatism of the vertebral column. The latter occurs bilaterally. It is not denied that these affections can be closely mimicked in hysteria, neurasthenia, and traumatic neurosis.

Attempted Criminal Abortion in a Nonpregnant Woman.—Zweifel mentions the frequency of this act and the frequency with which it escapes detection. Still the literature is remarkably scanty. The mistake as to preceding abortion is at times made in the clinic, when the obstetrician dilates the cervix and seeks to extract an ovum which never existed. The author's own case was as follows: Domestic, aged 24. Four years beforehand she had given birth to a child. Recently her menses hitherto regular, lasted but one day, and on the following month were absent, it was thought, but a few days later she began to flow profusely. There were no evidences of pregnancy, and the profuse bleeding was set down to artificial abortion. A tear was present in the cervix which readily admitted a probe into the corpus. Pregnancy was excluded by an examination of the uterine mucosa. Hemorrhage was arrested by a tampon. There was no doubt that after her one-day menstruation she had gone to a physician who had advised the usual mild measures until the time of the next period, when an attempt was made by the patient or some one else to terminate gestation with instruments. Four days later she began to flow.

Measles in a Child Complicating Typhoid.—Jastrowitz discusses the occurrence of such cases of which an example may be cited. The child, aged 3½ years, had been ailing for some days. A brother at the same time had a persistent diarrhea. The patient eventually developed bronchitis, which, with the history of fever, suggested a possible miliary tuberculosis. However, the rapid supervention of rhinitis, coryza, and exanthem showed that measles at least was present. After the rash had subsided there was no sign of defervescence at first. Then there were two days of low (subnormal) temperature and euphoria. Suddenly the temperature shot up, a continued fever running to about 40° C. daily. A bronchopneumonia came in evidence, disappearing by crisis after several days. The crisis was accompanied by diarrhea containing pus and typhoid bacilli. With the skin entirely clear of measles a fine typhoid exanthem could be made out. The spleen was found to be enlarged. The diarrhea of a brother has already been mentioned and sooner or later every member of the family could be shown to have typhoid in some form.

Radical Operation for Primary Carcinoma of the Lung.—Rotter states that there have been seventeen completely controlled cases of amputation of the lung for cancer and other maladies. There were 11 recoveries, as follows: 2 cases of tuberculosis, 7 cases of bronchiectasis, and 2 cases of tumor (one being Rotter's). There were six deaths, two being "vagus" deaths, 1 from collapse, 1 from acute pneumothorax and collapse, 1 from mediastinal emphysema, 1 from sepsis from necrosis of stump of hilus. The author's case was cancer in the right lower lobe and he had to remove not only the latter intact but other lung tissue. Patient was a man of 51, and the lesion began with severe pains *in situ*. The intervention was naturally of the most formidable kind and the radiogram taken afterward shows a great concavity at the interior half of the thorax. Vicarious emphysema has developed in the sound lung. In the mutilated lung respiration is aided even during repose of the auxiliary cervix muscles. After living 10 months patient succumbed to suffocation due to a complication of conditions. Small metastases of cancer were seen.

A Case of Phlebitis Without Thrombosis of the Sigmoid Sinus.—A. Cheatle reports the case of a child, aged 1 year and 11 months, who was admitted to the hospital on March 11, 1913, acutely ill with a mastoid abscess and a temperature of 103° F. At the operation on the same day it was found that the sigmoid sinus had been exposed by the disease. The sinus wall did not appear to be granulating, but felt and looked quite smooth, and appeared firm. The next afternoon, as the child was not relieved, and the temperature in the morning was 104.2° F. (without a rigor), the sinus was very thoroughly exposed; it appeared pale and "lumpy," and felt firm. On incising it no blood escaped. The jugular vein, which was collapsed and not thrombosed down to the combined facial and lingual, was then tied and divided. The sinus being thoroughly opened, it was then found that the firm feeling was due to great thickening of the wall, and that the lumen was exceedingly small and contained a little fluid blood without any thrombus. No flow of blood could be obtained even when a curette was passed nearly up to the torcular. No bacteriological examination of the sinus blood was made, as cessation of breathing occurred and the operation had to be finished in a hurry. The child was rather ill for four days, but after that recovery was quick and uneventful. The condition appeared to have been one of inflammation of the sinus wall, and the author thinks it is a question whether free exposure alone would not have sufficed.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

Compulsory Insurance in Germany.—Within the last year a new law governing compulsory insurance has been introduced in Germany. Heretofore compulsory insurance against sickness, invalidity, and old age extended solely to manual workers earning less than $500 a year, no similar provision having been made for the ever-growing army of brain workers employed in commerce and industry and whose salary exceeded this limit. Under the new law every employee whose work is not of a purely mechanical nature and whose salary is under $1,250 a year is compelled to insure under the new regulations providing for the creation of a special branch of insurance for the benefit of higher grade employees. This applies to every employee in business, factories, professions, such as teachers, actors, pharmaceutical assistants, etc., of both sexes, one-sixth of which will be females, also officers of the mercantile marine. The payments take the form of a fixed contribution payable each month, one-half of which has to be paid by the employer, over and above the employee's salary, and the other half has to be deducted by the employer from the employee's salary. The employer is required to see that every employee is duly insured. The total monthly contribution ranges from 40 cents to $6.65 according to the salary earned. Thus an annual salary from $750 to $1,000 entitles the monthly payment of $5, one-half the employer pays and the other half he deducts from the wage of the employee. In return for these contributions the insured employees will be entitled to claim a pension on reaching the age of sixty-five, or before if incapacitated for work, while in the case of death, the widow and children will receive an annual allowance. During the first ten years, or five years in the case of female employees, no benefits are payable, but after this period the insured can claim a pension which wil amount to one-quarter of the total contributions paid by and on behalf of the insured during that time. For instance, a clerk has been working for ten years at an annual salary of $800, and the total contributions paid during that time amount to $600, one-quarter of which, or $150, will represent the claimant's annual pension. For every year after the first ten, the pension will increase by one-eighth of the total contributions paid in after the first ten years, in addition to the quarter of the contributions paid during the ten years. Thus the clerk earning $800 would after twenty-five years' employment be entitled to a pension of $262.50 and after fifty years of $450. The pension payable to the widow, or to the widower if the deceased wife by her earnings supported him, will amount to two-fifths of the pension received by the deceased husband, or to which he would have been entitled at the time of his death. Each child in addition will receive an allowance equal to one-fifth of the widow's pension until the age of eighteen. The widow's pension will be paid up to her remarriage, at which time she will receive a lump sum equal to three years' pension in final settlement. Further, an employee who has been continuously incapacitated through illness for a period of twenty-six weeks, will be entitled to an allowance during his convalescence after this time and if special course of tratment is indicated in his case, likely to restore his working capacity, the insurance allowance must be used to defray the whole cost of such treatment, and during his absence from home his dependents will be entitled to receive a daily allowance amounting to three-twentieths of the last paid monthly contribution. The government has placed practically the whole administration of the scheme in the hands of both parties directly interested, these are the employer and employee, as the government does not contribute a cent. The emperor appoints only the director and the office clerks attached to the headquarters in Berlin, the administration, however, will rest in elected bodies consisting of an equal number of elected representatives of employers and employees. The central administration will rest in the hands of the director and two elected representatives of the employers and employees each, assisted by a board of twelve representatives of each party. There will be, also, local boards composed of an equal number of elected representatives of both parties, and disputes will be settled by specially constituted arbitration boards, and, if necessary, by a supreme board of arbitration attached to the headquarters in Berlin. The law forbids the employer to place any difficulties in the way of an employee elected for service on one of the boards, or in the performance of duties connected with the board, and of attending meetings. It is officially estimated that the entire cost of this new branch of insurance will amount to $37,500,000, half of which will have to be contributed by each party, so that as far as German employers are concerned, it will mean an extra annual charge to the cost of production of $18,750,000, and in manufacturing circles in Germany fears have been entertained that this fresh burden together with an extension in workmen's insurance and the rise in foodstuffs, might prove prejudicial to German exports in the fight for foreign markets against countries not possessing similar charges to be met by manufacturers. The principal point in the German government's reply to these fears was that the new measure would prove of great benefit to every business in that it would now permit an employer to rejuvenate his staff without having his older employees unprovided for, and in the end every business in consequence would prove more profitable owing to its increased productiveness.—George P. Forrester, F. C. S., in the *American Druggist and Pharmaceutical Record.*

Uric Acid Mistaken for Sugar.—The danger of diagnosing glycosuria in the absence of sugar, when uric acid is abundant in a urine, needs special mention. Uric acid has considerable power of reducing Fehling's solution. It seldom gives the copious brick-red or orange-yellow precipitate that is characteristic of abundance of sugar, but it may give just enough reduction or change of color to make it doubtful whether sugar is present or not. More than a few proposers for life insurance have suffered unfairly on this account; no such partial reduction should be regarded as due to sugar until the presence of glucose has been confirmed by other means, particularly the phenylhydrazine and the fermentation tests.—Herbert French, in the "Index of Differential Diagnosis."

Deutsche Verein für Versicherungs-Wissenschaft.—This body held its annual meeting in December. The subject for general discussion was "War and Insurance," under the following heads: insurance contracts and war; war mortality (statistics); war mortality (medical); injuries of war and insurance; transport insurance and war; fire insurance and war; social insurance and war.

Book Reviews.

Der klinische Blutdruck, besonders bei Veränderungen des Herzens, der Nieren und der Nebennieren. Von Olaf Scheel. Mit drei Tafeln and 12 figuren im text. Kristiania, 1912.

The experiments forming the basis of this book were performed in the clinics of the University of Christiania between the years 1907 and 1910. Three main topics are considered: 1. Blood pressure, its history, practical worth, etc. 2. Relation of the blood pressure to the size and function of the heart, normal heart and kidneys, valvular disease, nephritis and hypertrophy of the heart, amount of blood, diastolic pressure, etc. 3. Various influences upon blood pressure, mistakes, temporary changes, age, sex, respiration, body weight, hematemesis, diet, etc., nephritis hypertony, febrile disease; many items concerning the adrenals, as for instance edema of the adrenal, blood pressure in edema of the adrenal, amyloid adrenals, hyperfunction, pathological adrenalenemia, adrenal arteriosclerosis, and hypertrophy. The many detailed charts give a vast amount of data. The conclusion arrived at among others is that in the normal heart and kidneys there is a definite relation between blood pressure and weight of the heart. Further, that in valvular disease the relation as found between blood pressure and the functionating part of the left ventricle which aids the arterial system is such that the pressure is higher in aortic insufficiency and lower in mitral stenosis. In nephritis and hypertrophy of the heart the relation between the peripheral resistance and the size of the heart is disturbed, namely, the resistance has developed more than the weight of the heart. The balance between blood pressure and heart's weight in the nephritides is based on different niveaus than is normally the case. The bibliography includes the works treating of the subjects in the book. The very latest literature on the subject does not come under consideration.

The Bradshaw Lecture on the Diagnosis and Treatment of Incipient Pulmonary Tuberculosis. By David Bridge Lees, M.D., F.R.C.P. Price $1.25. London: H. K. Lewis, 1913.

In these lectures dedicated to the memory of Sir William Wood Bradshaw the author sets forth and elaborates on three statements of which perhaps only two can be considered somewhat novel and well worth a careful perusal and study. The first is that "the existence of an incipient pulmonary tuberculosis can be easily demonstrated by careful percussion (provided that during the examination of the front of the chest the patient is in the recumbent position with relaxed muscles) long before any bacteriological evidence is obtainable, and while the auscultatory evidence is still insufficient for a diagnosis." In the second statement the author emphasizes what has long been considered a maxim by all conscientious diagnosticians, namely, "that a negative bacteriological report is often fatally deceptive, and that to wait for the demonstration of bacilli in the sputum is like postponing the diagnosis of cancer until the glands are involved." The third statement is to the effect that "in the earliest stage of pulmonary tuberculosis it is always possible to obtain prompt and permanent arrest of the disease by the employment of the method of continuous antiseptic inhalation." The evidence on which this statement is based is given in a table of seventy cases, the clinical facts of which are stated in the appendix. Of tuberculin the author says: "It is a double-edged instrument. In skilled hands, if used with care and accompanied by close supervision and regular physical examination, it appears to be capable of giving some slight assistance in the treatment of pulmonary tuberculosis." As substances best suited and most efficacious for inhalation in pulmonary tuberculosis, creosote, thymol, eucalyptus, iodoform or terebene are mentioned.

The Influence of Monarchs. Steps in a new Science of History. By Frederick Adams Woods, M.D., Lecturer in Biology in the Massachusetts Institute of Technology. Price $2.00 net. New York: The Macmillan Company, 1913.

The author has for several years been a pioneer in a field which he designates the science of historiometry. By the application of scientific methods to history he hopes to be able to raise the standing of the philosophy of history and therefrom to derive many advantages. In the present volume he has considered the history of fourteen of the principal countries of the world from the eleventh to the eighteenth centuries and by a correlation of the personal characteristics of their monarchs during this time with the general classification of conditions in their country during their rule has arrived at the conclusion that the influence of the monarch was predominant in bringing about advance or retreat in his country. Out of 354 examples the correlation was perfect in 223, or more than 63 per cent. Presented as the author presents it the argument seems unanswerable and indeed there seems to be no logical reason why it should not be true. The book will prove an interesting one to the reader who is fond of history.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, etc., etc. Edited by Henry W. Cattell, A.M., M.D. Volume II, Twenty-third Series, 1913. Price $2.00. Philadelphia and London: J. B. Lippincott Company.

Twenty-three articles on diagnosis and treatment, medicine, neurology, legal medicine, etc., are included in this volume of the established Quarterly. Articles on paroxysmal hemoglobinuria, physiology of the heart, hemorrhage in the newborn, vaccines, and rape are worthy of special mention and contain valuable material. This number is well up to the standard set by the previous volumes of the publication.

Coprostasis: Its Causes, Prevention and Treatment. By Sir James Sawyer, of London, Doctor of Medicine; Fellow of Royal College of Physicians; Consulting Physician to the Queen's Hospital, Birmingham, etc. Price 2s. 6d. net. Birmingham: Cornish Bros., 1912.

This small volume is made up of Chapters VIII to XIII of "Contributions to Practical Medicine" in its fifth edition. In them are discussed habitual constipation, intestinal obstruction, backache due to constipation and an ointment for hemorrhoids advised by the author. It is brief and makes interesting reading.

Die Sanitätsausrüstung des Heeres im Kriege. Mit Genehmigung des Kongl. Preussischen Kriegsministeriums unter Benutzung amtlicher Quellen, bearbeitet von Dr. W. Niehues, Oberstabsarzt im Kriegsministerium. Mit 239 Abbildungen auf 73 Tafeln und im Text. Price Mk. 24. Berlin: A. Hirschwald, 1913.

This voluminous work aims to describe with the aid of many illustrations the complete sanitation equipment of the various medical departments in the German army up to January 1, 1913. In introducing the description of the larger apparati, as wagons for the injured in the artillery or infantry, emergency knapsacks, dental cases, etc., the historical development of each particular piece is given. The numerous photographs make the curtailed description of each piece possible and give a clearer conception of them than could be gained by words alone. The book is divided into chapters on the equipment of all the members of the army, of the sanitary corps, of the carriers of the wounded in the infantry, of the sanitary officers, field apothecaries and dentists, equipment of the troop as a whole, of the sanitary company; field hospital and hospital train; the sanitary provision halting depot.

Golden Rules of Diagnosis and Treatment of Diseases. Aphorisms, Observations, and Precepts on the Method of Examination and Diagnosis of Diseases, with Practical Rules for Proper Remedial Procedure. By Henry A. Cables, B.S., M.D., Professor of Medicine and Clinical Medicine of the College of Physicians and Surgeons; Consultant at Jefferson Hospital; formerly House Physician at Alexian Brothers' Hospital, St. Louis. Second Edition, Revised and Rewritten. Price $2.25. St. Louis: C. V. Mosby Company, 1913.

The book has been entirely reset and chapters added on infectious diseases. The entire work has been rewritten and new rules have been added. The book has been a very successful one and is presented with the firm belief that a study of it will assist in making a correct diagnosis and indicate the proper therapeutic measure, as well as aid in fixing in the mind valuable information that can be readily recalled when needed.

Fibroids of the Uterus; Their Pathology, Diagnosis and Treatment. By Sir John Bland-Sutton, F.R.C.S., Surgeon to the Middlesex Hospital and Its Cancer Charity. Thirty-nine illustrations. Price 4/6 net. London: Science Reviews, 1913.

This is one of the London Series of Handbooks and an attempt is made to set down in narrative form a summary of their knowledge of uterine fibroids which includes the natural history, the diagnosis and the best methods of removing them. At the end of the more important chapters a list of references is added; he believes that an inspection of such lists is instructive, for some of them serve as milestones indicating the progress in pelvic surgery. This little book should commend itself to all.

The Catarrhal and Suppurative Diseases of the Accessory Sinuses of the Nose. By Ross Hall Skillern, M.D., Professor of Laryngology Medico-Chirurgical College; Laryngologist to the Rush Hospital; Fellow of the American Laryngological, Rhinological, and Otological Society; Fellow of the New York Academy of Medicine; Member of the Society of German Laryngologists, etc., etc. Price $5.00. Philadelphia and London: J. B. Lippincott Company, 1913.

This is the first complete textbook in the English language on the subject of the catarrhal and suppurative diseases of the nasal accessory sinuses. It is hardly necessary to emphasize the importance of a recognition of these diseases as the chief factor in what is commonly regarded as chronic nasal discharge and in the production of painful local and reflex symptoms, to say nothing of the serious complications from involvement of the neighboring cranial and intracranial structures. The general practitioner cannot afford to ignore the significance of many symptoms, such as headache, which are frequently indicative of disease of one of the accessory sinuses. To the rhinologist the chief value of this book lies in its gathering together the threads of knowledge on the subject that are scattered throughout the literature, chiefly foreign, and in presenting a comprehensive guide in the diagnosis and treatment of the sinus affections. The work is eminently practical. The illustrations are numerous, artistic, and particularly helpful in elucidating the text. The frontispiece with its superimposed transparent drawings, after the manner of the paper anatomical manikin, showing the different strata of the lateral wall of the nose, is a most ingenious didactic contrivance and exemplifies the author's efforts to make his work as lucid as possible. The bibliographical references indicate a vast amount of research. The book may be recommended to the student and practitioner as a superb and up-to-date textbook.

Disease in Milk. The Remedy Pasteurization. By Lina Gutherz Straus. New York, 1913.

The author, Mrs. Nathan Straus, is to be congratulated upon her editorial skill and rare enthusiasm in compiling a volume that forms a valuable addition to medical literature, chiefly because it records the growth of a private philanthropic enterprise, which has in many localities resulted in the municipal enforcement of milk pasteurization. With almost prophetic vision Nathan Straus perceived two decades ago the important relation between impure milk and infant mortality, and his creation of infant depots at which pasteurized milk was dispensed inaugurated a movement that was really threefold: a campaign for the reduction of infant mortality, the world-wide establishment of infants' milk-depots, and the general pasteurization of milk supplies as a public sanitary measure. Any one of these achievements would have been a source of pride to any man. The fact that the name Nathan Straus has become almost synonymous with the campaign for the general pasteurization of milk, is not to be attributed to egotistic exploitation, but rather to the fact that the influence of a strong personality, backed by abundant financial means, is infinitely more effective in directing large philanthropic movements than the mere bloodless and silent power of wealth.

What Heart Patients Should Know and Do. Suggestions for Persons Suffering from Diseases of the Heart and Blood-Vessels. Exercise, Diet, Prevention, etc., and Advice as to the Regulation of Their Lives. By James Henry Honan, M.D. Rush Medical College (University of Chicago), M.D.; Imperial Friedrich Wilhelm University of Berlin, M.D.; Special Lecturer on Cardiovascular Disease in the University of Georgia; Honorary Member of the American Medical Association; Honorary President and formerly Active President of the Anglo-American Medical Association in Berlin; Mitglied des Vereins für Innere Medizin, Deutschland; Mitglied des Aerzte Verein zu Bad-Nauheim, etc. Price $1.20 net. New York: Dodd, Mead & Company, 1913.

The object of this book is to give encouragement and hope to those who know they have heart trouble; to lead those who are unconscious that they have heart trouble to ascertain their deficiency or weakness without arousing their undue anxiety; to help both to make the most of their lives by avoiding those things which so often lead to the needless and tragic sacrifice of men and women; and to warn the well from doing those things which cause heart, blood-vessel and kidney diseases. The book gives general and special advice, treats of habit, diet, rest, baths, exercise, etc., in their relation to heart trouble.

Practical Guide to Diseases of the Throat, Nose and Ear. For Senior Students and Junior Practitioners. By William Lamb, M.D., C.M. Edin., M.R.C.P. Lond. Honorary Surgeon, Birmingham Ear and Throat Hospital. Third edition. Price $2.75 net. New York: William Wood & Company, 1913.

In this third edition the subject matter has been revised and brought up to date as far as that is possible in an elementary work, and short sections have been added on such practical points as oral sepsis, occasional risks attending the tonsil and adenoid operation, tonsillectomy, submucous resection of the nose, intranasal operation for chronic autral suppuration, danger signs in ear disease, the conservative mastoid operation, the examination of the labyrinth, etc. The book is fully illustrated and gives a clear but elementary outline of the subject.

Sex. Its Origin and Determination. A Study of the Metabolic Cycle and Its Influence in the Origin and Determination of Sex, the Course of Acute Disease, Parturition, etc. By Thomas E. Reed, M.D. New York: Rebman Company, 1913.

In this book the general methods of reproduction and the various theories of sex determination are reviewed. The author then demonstrates the primitive hermaphroditism of all animal organisms and the bisexual rhythm in the germ plasm. He discusses the influence of the lunar month and lunar day in its relation to the phenomena of menstruation, the progress of labor and the determination of sex. In discussing the last subject he advances the theory that the time of conception is a determining factor as regards sex; if the ovum is impregnated during the positive cycle, a male results; if during the negative, a female. The book is interesting reading as a collection of theories and biologic facts bearing on the subject of sex determination, but the theory advanced offers about as many weak points as its originator has found in other theories of this kind, and we may venture to predict that the last word on this subject has not yet been said.

Hygiene of the Nursery. Including the General Regimen and Feeding of Infants and Children; Massage, and the Domestic Management of the Ordinary Emergencies of Early Life. By Louis Starr, M.D., LL.D. Eighth Edition, with twenty-six illustrations. Price, $1.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

The seven previous editions apparently have not exhausted the efficiency of this manual, for which the demand is still undiminished. This popularity is probably to be attributed to the author's soundness of views and command of a clear and forceful style. There is little that one can criticize. Possibly too many methods of infant feeding are described, which cannot but confuse the parent looking for specific advice. May one not suggest that the term "humanized" milk be abandoned as misleading? No milk can be "humanized" in the sense that it can even slightly approximate the wonderful biological properties of the human product.

Food and Feeding in Health and Disease. A Manual of Practical Dietetrics. By Chalmers Watson, M.D., F.R.C.P.E. Assistant Physician, Royal Infirmary, Edinburgh: Editor of the "Encyclopedia Medica." Second edition, revised. Price $5.00. New York: William Wood & Company, 1913.

Recognizing that the subject of dietetics has no recognized place in the teaching of medicine, the author aims at providing a practical epitome for the dietetic student. The elements of physiology with reference to food and digestion, the nature of foods, the normal laws of feeding are reviewed. Some attention is given to kitchen processes. Less attention than is usual in works on diet is devoted to the chemical composition of the heat values of food and more to its influence on the digestive and bacterial processes in the digestive tract. The chapters on the special diets in the various diseases have been collaborated with the assistance of specialists in their special lines. Dr. A. Dingwall Fordyce prepared the chapter on infant feeding in health and disease, and G. W. Watson, J. H. Gibbs, F. Gardiner, Andrew Hunter, G. Lyon, Malcolm Campbell, C. B. Paul and B. C. Watson have given their assistance in their individual fields. There is an appendix which gives the results of the experimental researches carried out by the author and others in the Physiological Laboratory of Edinburgh University since 1900. Every physician will find in this work many suggestions of real practical value in feeding the sick which will give him assistance in solving some of his most puzzling problems; and furthermore it can be read with profit by every nurse and mother and should be kept in a convenient place for reference.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF SURGERY.

Stated Meeting, Held April 4, 1913.

DR. A. S. VOSBURGH, CHAIRMAN PRO TEM.

Large Defect in Abdominal Wall Repaired by Silver Screen Method, "Willy Meyer" Modified.—Dr. A. JUDD presented this patient and read the report.

Case of Chronic Infection of Gall-Ducts Cured with Schäner's Vaccines.—Dr. A. JUDD presented this patient and read the report.

Open Operation for Congenital Dislocation of Hip.—Dr. JOSEPH WIENER reported the case of a girl of nine years who was admitted to Mt. Sinai Hospital, September 19, 1911. Her family and previous history was negative. When the child began to walk at the age of one year (eight years ago) the mother noticed that she had a limp. There was no trauma, no pain, no fever, no chills, but she had kept a waddling gait up to the present time. There had been no treatment during the entire period. The physical examination showed limited motions of the left hip joint. There was full flexion, some limitations of extension, outward and inward rotation were exaggerated, adduction was almost to 90°, and abduction was limited. When the thigh was flexed on the abdomen, then abducted, there was considerable limitation. Motion of the thigh upward and downward was possible. The head was felt behind and above the acetabular cavity. When the femur was drawn down, left Scarpa's triangle appeared as a deep fossa, and the adductors and sartorius were rendered tense. From the anterior superior spine to the external malleolus on the left side the distance was 54.5 cm., on the right side 59 cm. (about 2 inches shortening); from the anterior superior spine to the posterior border of the great trochanter on the left side the distance was 8.5 cm., on the right 7 cm. Bryant's triangle showed on the left 1 cm., on the right 5.5 cm. On November 1 an attempt at reduction under ether anesthesia was attempted. Relxation of the muscles was complete after extension for two weeks. Hyperextension, then flexion and circumduction and counter-pressure on the head of the bone failed to reduce the dislocation after several attempts. On November 11 an open operation was performed. A curved incision was made over the hip joint, the muscles were split, the joint reached and opened, the capsule being cut anteriorly above and below. Exploration then discovered that the head of the femur was anteverted on its neck, and that the acetabulum was abnormally short, small, and shallow. The acetabulum was enlarged and deepened with a chisel, the finishing being done with a sharp spoon. The thigh was flexed, abducted, and externally rotated in the efforts at reduction; on repeated attempts the femur jumped into place. This was followed by extension and internal rotation. The capsule was sutured with No. 2 chromic gut, the muscles with No. 2 plain gut, and the skin with silk. Plaster of Paris dressing was then applied with the leg in extension and internal rotation. The cast was removed and reapplied on December 3, and again on January 3. The child subsequently walked very well, with a freely movable hip. X-ray pictures of the case were shown.

Dr. A. S. VOSBURGH asked Dr. Wiener what the functional result was.

Dr. JOSEPH WIENER replied that it was very good. There was no shortening. The child had attended school all winter and went up several flights of stairs every day.

Dr. DEXTER D. ASHLEY said that Dr. Wiener had certainly obtained a very admirable result in this open operation for the reduction of the congenitally dislocated hip. If we could get such results every time it would be the desired procedure. There were a certain number of cases that with the best of endeavor and skill were not curable by the bloodless reduction. However, according to late reports of some of our best orthopedic surgeons, 90 per cent. could be made perfect by the bloodless procedure when taken at the proper age. Dr. Lorenz, eleven years ago, when approaching his one-thousandth ease, stated with some hesitancy that he never expected to do any other than the bloodless operation. For those who may have forgotten, and regarded Dr. Lorenz only as a bloodless surgeon, I wish to say that he had done two hundred cases by the open method, described as the "Hoffa-Lorenz method," before he did the bloodless reduction. There had been some intimation that the bloodless reduction did not give as stable a hip, and was less accurate in its procedure than the open operation. According to the statistics of the Boston orthopedic men, who held very late to the open method, the percentage of stability by the open operation is not any greater than by the bloodless method; there are just as many relapses. When we take into consideration the early passive motion that must be instituted in this open operation, we have the explanation of the cause of the lack of stability. Dr. Ashley said he had done something over two hundred cases, and could say that when he had reduced the hip, getting a stable position, and had been able to follow up the case, he had never had a hip redislocate. In other words, one could predict, almost with certainty, the outcome of the case at the time of operation. He had been asked on several occasions to what extent the bloodless method was accepted and used by orthopedic surgeons and wished to state that it was the only method that was in general use to-day.

Acute Septic Infarcts of the Kidney: Nephrectomy: Recovery.—Dr. ANTHONY H. HARRIGAN reported the case of a woman, twenty-one years of age, a housewife, who was admitted to Fordham Hospital, service of Dr. William P. Healy, January 24, 1913. The family history was negative. Her habits were good. She was married ten months ago and was now pregnant four months. Her present illness began ten days ago when an alveolar abscess opened spontaneously. Two days later she suffered from backache which was severe. The following day she had a severe chill. The pain persisted and became more severe. The chills occurred daily. The temperature had ranged between 100° and 103.5° F. The day before admission the pain became general over the abdomen, with its maximum in the right lumbar region. There were no bladder symptoms. The physical examination showed a pulse of 80 and a temperature of 99° F. The patient appeared to be gravely ill. The examination of the abdomen revealed the enlarged pregnant uterus. The right kidney was enlarged and tender. The extreme point of tenderness was in the right costo-vertebral angle. The leucocyte count was 34,800, the polymorphonuclears 88 per cent., the large mononuclears 6 per cent., the small mononuclears 5 per cent., and the transitionals 1 per cent. The examination of the lungs, liver, spleen, and all the regions was negative. The urine contained albumin and pus cells. In the diagnosis two things were considered, pyelonephritis and acute septic infarcts of the kidney. The latter diagnosis was considered in view of the history of the alveolar abscess. A right oblique lumbar incision was made and the kidney easily delivered and inspected. The surface presented innumerable foci of suppurations. The diagnosis of septic infarcts was made and nephrectomy was decided upon. The pedicle was clamped and divided, and the kidney removed. The pedicle was transfixed in several places and ligated with chromic catgut. The ureter was ligated separately with catgut. The wound was sutured in layers up to the upper angle when a plain gauze drain was passed to the ligated pedicle. The recovery was uneventful. The patient did not abort. There were no signs of kidney insufficiency during the first twenty-four hours. After the operation the temperature dropped to normal and remained there. The patient was discharged in excellent condition. The wound was closed except for a short sinus in the upper angle. It was a staphylococcus infection.

Dr. WILLIAM H. LUCKETT asked how it was possible for him to make a diagnosis of septic infarct.

Dr. HARRIGAN replied that the diagnosis was made only after exposing the kidney.

Dr. F. KAMMERER said that he was much interested in Dr. Harrigan's case, as the patient was a woman and the right kidney had been the one affected. In a discussion of Dr. Brewer's paper at the American Surgical Association, in 1908, he had referred to four cases of unilateral hematogenous infection of the kidney which had been under his care. These cases were more extensively described in the *Festschrift* for the German Hospital of the city of New York, published in 1909. In this later publication the speaker had called attention to the fact that these infections occurred much more frequently in women than in men, and were most always situated on the right side. Of 28 cases, which he was able to collect at the time, 16 belonged to Dr. Brewer, 8 to Dr. Cobb, and 4 to himself. Of these, 24 occurred in women. In 3 of these 24 cases the kidney had been the seat of some prior disease, but in the remaining 21 the infection had, to all appearances, developed in a previously healthy kidney. Furthermore, of these 21 nineteen were on the right and only two on the left side. These numbers, in connection with the fact that three of the speaker's cases were affections of the right side in women, had suggested to him the probability of a connection between unilateral hematogenous infection and a movable kidney. Two years later Cotton, in the *Annals of Surgery* (November, 1911), offered the same

explanation, evidently in ignorance of the speaker's previous publication. Cotton reported two cases in which an excellent result had been obtained by decapsulation of the kidney as opposed to nephrectomy. In the *Festschrift*, previously mentioned, Dr. Kammerer had suggested this plan of treatment, and he was glad to see that it had been so successfully carried out. His suggestion was to free the kidney to its pedicle, to remove the capsule exposing the small septic foci, which at the beginning of a hematogenous infection were generally confined to the cortex, to wrap the organ in loose gauze and to await further developments. If the septic symptoms did not subside the organ could, a few days later, be easily removed by throwing a ligature around the pedicle. That in many such cases the kidney could be saved, Cotton's experience had demonstrated.

Dr. A. S. Vosburgh reported the case of a girl who was admitted to Bellevue Hospital with the diagnosis of appendicitis. She gave a history of having struck her flank on the side of a table, which was followed by pain, and she was ill for some time after. When Dr. Vosburgh examined this mass on the right side it seemed too huge for appendicitis, and he thought that probably there was a suppurative nephritis of the right side to deal with. A preliminary incision was made and a mass was found that was retroperitoneal. The incision was sewn up and the kidney was exposed from behind. There was a dilatation of the kidney and an abscess outside the kidney. This organ was very adherent. It appeared to him that if the kidney was left there would follow a very prolonged suppuration. The kidney was enucleated at that time. This kidney was movable and by its descent had produced an obstruction of the ureter. The previous attacks of pain she complained of were simply attacks of colic.

Resection of Esophagus for Carcinoma.—Dr. Franz Torek. The first successful case of resection of the thoracic portion of the esophagus for carcinoma. The tumor was situated in the middle portion of the esophagus, beginning just below the arch of the aorta and extending one and three-quarters inches down. Dr. Torek called attention to Sauerbruch's position that only the carcinomata in the portion near the cardia should be resected. He also called atttention to the fact that the carcinomata near the cardia occur less frequently than those in the middle portion, and that they are also more frequently associated with metastases. The carcinomata in the middle portion therefore played a more important rôle in the problem of cancer of the esophagus. Among the dangers in the operation were injury to the vagi and leakage from the oral stump of the esophagus after resection. To avoid the former better access was needed. The patient was a woman, 67 years of age, on whom he had performed a gastrostomy some time previous. He made an incision through the whole length of the seventh intercostal space, from the posterior end of which it was extended upward by cutting through the seventh, sixth, fifth, and fourth ribs near their tubercles, which gave an excellent access to the parts. Extensive adhesions between lung and parietal pleura were separated. The portion of the esophagus below the tumor was lifted out of its bed after preparing the vagi aside. Over the tumor the dissection of the vagi was more difficult, requiring the division of some branches crossing it. During this procedure the pulse remained steady, between 93 and 96. The dissection of that part of the esophagus which passed behind the arch of the aorta proved difficult. It was accomplished by dislodging the aorta after dividing a number of its thoracic branches. Posteriorly the tumor was attached to the left bronchus, which was cut during the process of separating the tumor from it. The cut in the bronchus was afterward sutured with silk. The dissection of the esophagus was then continued all the way up the pleural cavity to the neck. It was then divided with a cautery at a safe distance below the carcinoma, after double ligation, the lower stump was invaginated, and the upper part brought out through an incision in the neck at the anterior border of the sterno-cleido-mastoid muscle. Thus an infection of the pleura from the esophagus was rendered impossible.

The thorax was closed and the esophagus transplanted under the skin of the chest, the open end being sutured to the skin at an incision made for the purpose. The thorax was not drained. Anesthesia by tracheal insufflation was employed. The patient made a good recovery. On the seventh day, when the last stitches were removed, the wound was completely closed. Feeding was done by introducing the upper end of a gastrostomy tube into the end of the esophagus; what the patient swallowed passed through this rubber tube into the stomach. Dr. Torek mentioned that there were several methods of esophagoplasty that could be employed.

Dr. Willy Meyer said that since 1904 surgeons had tried without success to save the patient's life after resection of the esophagus for carcinoma. As to the cause of death, it was particularly the so-called vagus death that took the patients away, and it can be stated that involvement of both pneumogastric nerves above or behind the aortic arch rendered the case an inoperable one. Sauerbruch succeeded in pulling the patient through the operation as such, excising carcinoma at the cardia with following esophagogastrostomy by button. Two weeks later the patient contracted pneumonia of the right lower lobe and died. Ach of Munich operated upon a similar case. He also transposed the oral esophageal stump (as Torek has done in his case). Both pneumogastrics had to be cut below the aortic arch. The gastrostomy fistula became insufficient and caused the patient's death on the 17th day after operation. Now, in this year, 1913, they were so fortunate as to be able to record two successful cases within nine weeks, Dr. Torek operating on March 14 on a carcinoma situated behind the aortic arch, in a female patient, 67 years of age, and Zaaijer of Leiden, Holland, for a carcinoma of the cardia involving the lower end of the esophagus in a male patient of 55 years, January 9. Torek's case was undoubtedly the first in which a carcinoma situated in the upper portion of the esophagus in the neighborhood of the aortic arch had been removed with recovery of the patient. It proved the correctness of the stand taken with regard to thoracic work at the German Hospital, namely, to attack a carcinoma of the esophagus, no matter where in the course of the tube it might be situated, and not to confine operations to tumors in the lower end of the esophagus. Torek, and according to the report, it seemed Zaaijer, too, found conditions such that they could prepare off both pneumogastric nerves. *Early diagnosis and early operation*, therefore, is the watchword. The evolution of the surgery of the esophagus has of late been exceedingly rapid. A year ago their efforts were confined to proving the possibility of resection of the growth in cases of malignant stricture of the esophagus. To-day they not only considered the possibility of removal of the tumor, but also the construction of a new esophagus, or the reconstruction of what had been left within the thorax. In connection with the latter efforts, the method of gastrostomy recently proposed by Jianu had given a great impetus to this kind of work. A patient thus operated upon was recently presented by me before the New York Surgical Society. The patient was a woman, 46 years of age, in whom the free end of the Jianu tube reached up to the cartilage of the third rib. In transposing the oral end of the esophagus extrathoracically and subcutaneously downward, both ends of these tubes might meet at once and be united by end-to-end suture, representing the so-called extra-thoracic esophagoplasty. If the transposed oral stump proved to be too short, a subsequent skin plasty must complete the work, except the wearing of a rubber tube connecting both openings should satisfy the patient. The speaker added that he was sure he voiced the sentiment of every one in the audience in offering hearty congratulations to Dr. Torek.

Acute Diverticulitis of Sigmoid.—Dr. Henry H. Janeway presented this patient. For three months preceding the date of operation the patient had been troubled with vague abdominal pain, constipation, anorexia, and indigestion. These symptoms became much intensfied two weeks before operation, though the bowels still acted with cathartics, and to them were added nausea, vomiting, marked abdominal tenderness, and pain, chills, fever, and sweating. Dr. Janeway first saw the patient on July 18, 1912. The examination elicited an area of maximum abdominal tenderness and rigidity two inches below the umbilicus and one inch to the left of the middle line. The abdominal rigidity diminished in degree the further from this area palpation was made. No mass could be felt (the patient was fat). The temperature was 102.6° F. The leucocytes numbered 16,500, the polynuclear forms were 79 per cent., and the mononuclears 21 per cent. Operation was performed four hours after Dr. Janeway saw the patient. A median incision was made and a pint of fecal pus was evacuated. An opening into the sigmoid was identified and apparently was above the meso-sigmoid at the angle of juncture of the horizontal and vertical portions, *i.e.* in the bend where the descending vertical portion of the sigmoid continuing the descending colon bent to the right to form the horizontal portion of the sigmoid. The pus was mopped out, and rubber drain tube was inserted. The patient made an ideal recovery, the fecal fistula healing in three or four weeks' time.

Epithelioma of the Esophagus, Illustrating a New Method of Gastrostomy.—Dr. Janeway presented this patient who was operated on January 6. A gastrostomy opening was made by a new method which was made pos-

sible by a small plastic procedure on the anterior wall of the stomach, which had the following characters: (1) The operation could be performed under local anesthesia through a small one and a half inch incision. (2) The new fistula was lined with mucous membrane and, therefore, would not spontaneously close, and consequently it was not necessary for the patient to wear a tube constantly. (3) The new canal was furnished with a natural sphincter in the rectus fibers, and with a valve closure at its inner extremity preventing leakage.

A New Form of Insufflation Apparatus (Portable).—Dr. JANEWAY exhibited this piece of apparatus for intratracheal anesthesia. It had the following features: It weighed fifteen pounds, and measured 4 x 14 inches. It could be readily taken apart and could be carried about in a small handbag. It was supplied with a motor running upon both alternating and direct currents, a blower delivering ninety cubic feet of air an hour, in other words, twice the amount calculated as necessary for the large permanent plant in Roosevelt Hospital. In fact, this was the same blower adopted by the layer machines. The apparatus was also furnished with a rheostat ether flask, air filler valve controlling the amount of ether used, and manometer and safety blow-off valve.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Meeting Held April 21, 1913.

THE PRESIDENT, DR. REYNOLD WEBB WILCOX, IN THE CHAIR.

Intestinal Adhesions: Bacteriologically, Experimentally, and Surgically Considered.—Dr. ROBERT T. MORRIS said that from time to time he hoped to bring before the society new points that were developed in the course of study of the subject of intestinal adhesions of insidious toxic origin, which promised to become one of the most important subjects ever taken up by the medical profession. In former years we had considered that a patient either had a good deal of peritonitis or none at all. The midway position, we were now coming to understand, was much more important, for patients who had insidious peritonitis, without symptoms leading to its classification as such, were far more common than those who had suffered from the more clearly recognized forms. The adhesions of the attic of the abdomen interfered with gastric and duodenal motility, and also caused at times obstruction of the bile ducts. They frequently gave rise to pain in the epigastrium, and were to be found to some degree in almost every adult who was examined with reference to this point. We had to distinguish between attic adhesions and peritoneal defects common in the upper part of the abdomen, and also to distinguish between such adhesions and the more recently described Lane's kink and Jackson's membrane, which apparently belonged in the same toxic category. The latter conditions seemed to represent a hyperplasia of connective tissue, like that found in Dupuytren's contraction of the palmar fascia, and specimens of the connective tissue from Lane's kink, Jackson's membrane, attic adhesions, and Dupuytren's contraction could hardly be distinguished from each other on microscopical examination. In Dupuytren's contraction of the palmar fascia the hyperplastic connective tissue was more dense, because of the density of the parent tissue, while with the Lane kink, Jackson's membrane, or attic adhesions it was more loosely arranged, on account of the character of the parent tissue in these regions. Adventitious connective tissue was found also at the hepatic and splenic flexures of the colon. Examination of adhesion tissues for bacteria sometimes resulted in finding the colon bacillus, but in many cases no bacteria at all were found. It was probable that the toxins alone made their way through the bowel wall, causing toxic injury to cell protoplasm, with the resulting changes. The anaërobic bacteria were particularly prone to do this when there was intestinal stasis. These toxins were probably like those which made their way through the walls of the bile ducts and the gall bladder, excepting that in the latter case they represented a supply beyond the metabolizing ability of the individual for their disposal. Unmetabolized toxins poured out of the liver upon the duodenum, and probably excited at that point the secretion of hormones of abnormal character, and these stimulated abnormal secretion from the mucous glands of stomach and bowel. We had then a vicious circle established. The patients who were most subject to peritoneal adhesions of insidious toxic origin belonged to the neurasthenic group, the class of persons who seemed to have originally defective ductless glands, and who were otherwise deficient in the factors of protection which guarded against toxic injury in more perfectly developed individuals.

Dr. ANTHONY BASSLER said that while the surgical standards of drainage and extirpation of pathological tissues answered well in the whole domain of surgery, in the present subject more than these should be given consideration, because we were dealing with biology. It was not simply a matter of intestinal stasis. We must remember that the bowel might be matted into one mass by chronic peritonitis, so that great interference with peristalsis existed, and still intestinal toxemia not be present. Many cases of acute intestinal obstruction, as well as of those of a chronic type, were not accompanied by toxemia. The matter of intestinal stasis, an important one in this connection, was far from being proved, and in medicine it should always be remembered that the coexistence of two phenomena did not prove that they stood in the relation of cause and effect. Adhesions took place in the pia, pleura, pericardium, and joint cavities only because of infection with bacteria, and the same was true of the peritoneal cavity. In his opinion, all adhesions here directly bacterial in nature. It had been proved conclusively that bacteria can pass through a normal mucous membrane of the intestine, and, as a fact, they often did so. The subject was bound up in the bacteriology of the intestines, and this was further shown by the fact that the upper part of the small intestine, where there were but few bacteria, was practically free from adhesions. Then, most of the adhesions were found in those parts of the intestines where the veins and lymphatics emerged, as, for instance, the anterior band of the colon. Lastly, his studies had suggested that the bacteriology of the intestinal canal in adhesion cases was never normal. There were some ten forms of anaërobes of the bacilli class alone which were responsible for adhesions. Recently he had isolated a new bacterium which was commonly present in the stools of cases where there were marked adhesions, and which, when grown in culture and thrown into the intestinal canal of dogs, would produce pericolonic adhesions after a few injections. As to splanchnoptosia being responsible for adhesions, he would say that splanchnoptosia was due to intestinal toxemia, because in his studies of four autopsy cases of splanchnoptosia he had been able to prove that distinct degeneration of the sympathetic plexuses of the abdomen existed. Thus he felt that a toxemia affected the neuromuscular structures of the stomach and intestines, and then the extrinsic nerves; making possible the production of dilatation of local or generalized character. The splanchnics, as was known, were the inhibitory agents of the hollow abdominal viscera. Thus, with the toxemia persisting, degeneration took place in the sympathetic system of the abdomen by reason of the disturbing effects on the nutrition of the abdomen as a whole; while adhesions might ensue as the final result of the toxemia, plus bacterial extravasation.

Dr. WARD J. MACNEAL said that peritoneal adhesions were either fibrinous or fibrous. The former were but temporary, and either disappeared or became organized into fibrous adhesions. The fibrinous adhesion was produced by a general peritonitis or by a localized injury to the peritoneum. It was difficult to conceive of such localized injury occurring as a result of the penetration of soluble bacterial toxins through an intact intestinal wall, and it would seem that the local injury was most frequently caused by a localized infection of the subserous tissues or by bacterial invasion of the serosa itself. The injury to the serous coat brought about a precipitation of fibrin which served as a weak bond of union to some contiguous structure. If this fibrous union organized into fibrous tissue, a typical firm adhesion was the result. It was the latter type with which the physician and the surgeon had to deal. Such a fibrous adhesion was of the same order as a scar, and it might be impossible to arrive at any reliable conclusion as to the original etiological factors by the examination of such a scar. In order to study the etiology of peritoneal adhesions resort might best be had to experimental surgery, to ascertain the exact conditions which determine the production of adhesions and to distinguish them from the circumstances under which the formation of adhesions does not occur. A series of careful observations along this line had recently been reported by Adams in his Hunterian lecture before the Royal College of Surgeons. He had been able to produce both infected and bacteria-free adhesions in the peritoneal cavities of guinea pigs and rabbits. Noninfective adhesions were induced by destructive injury to the peritoneum, but with greater certainty by the introduction of foreign bodies (such as cotton sponges and drainage tubes) into the peritoneal cavity. Often these ad-

hesions would subsequently become infected by the penetration of bacteria from the lumen of the intestine. Extravasated blood in the peritoneal cavity rarely caused adhesions unless it had become infected. Infection of the peritoneum, and especially the introduction of infected foreign bodies, proved to be a ready method of causing adhesions. The omentum, Dr. MacNeal said, was one of the structures which most readily became adherent to an area of injured peritoneum. This was in part due to its wide range of excursion, and in part to the rapidity of absorption of foreign material by its lymphatics. The movements of the omentum were wholly passive, and depended upon the active movements of other structures, the most important of such movements being intestinal peristalsis.

Dr. Robert Coleman Kemp thought the profession owed a debt of gratitude to Dr. Morris for his careful investigation regarding the etiology of intestinal adhesions. The so-called attic of the abdomen he believed to be of great pathological importance, and it was Dr. Morris who first called our attention to the fact that the "spider-web" adhesions emanating from the diseased gall-bladder and involving the pylorus or upper duodenum, produced dilatation of the stomach, and at times even hemorrhage; simulating gastric ulcer with commencing pyloric stenosis with which he himself was in accordance. Dr. Morris held the view that the milder types of adhesions of web-like character resulted from various bacterial toxins emanating from the intestinal tract—in some cases those of the colon bacillus, while in a few instances he had found a few colon bacilli present. Briscoe had reported in the *Lancet* several instances of the matting together of the pelvic viscera by an exudate, which, on microscopical examination and culture, was proved to be caused by the colon bacillus. Turck, as would be remembered, had fed colon bacilli to dogs and produced gastric ulcer. It was extremely significant that gastric and duodenal ulcer were found with considerable frequency in association with gall-bladder infection and chronic appendicitis, as such ulcers were undoubtedly the result of some embolic process of toxic origin. The speaker said he was inclined to take the view of Dr. Morris that in many instances gastric and duodenal ulcer could be attributed to local endarteritis caused by the toxins of intestinal bacteria, particularly the colon bacillus, or to infection by these organisms. Secondary gastric ulcer had also developed from the erosions of achlorhydria hemorrhagica gastrica, and, moreover, adhesions frequently occurred with ulceration of the gastro-intestinal tract.

The Relations of Adhesions and Intestinal Angulations Resulting from Enteroptosis to Chronic Constipation; Personal Observations.—Dr. Robert Coleman Kemp read this paper, which was illustrated with a number of large radiographs taken by Dr. Sinclair Tousey. In making the diagnosis of this class of cases, he said, the symptoms and physical signs, as well as the radiograph, should be taken into consideration in connection with the radiograph. For example, in one case showing a portion of the transverse colon lying well down in the pelvis there was no evidences of interference by adhesions to the passage of bismuth. Only the angulations and displacement could be determined by the *x*-ray, but the history and the physical signs were conclusive. Subsequently to the removal of a diseased appendix this patient suffered from a local peritonitis, evidently having its origin at the stump of that organ, and there had been persistent tenderness over that region for several years. Without doubt there were adhesions binding the descending arm of the transverse colon to the caput coli and ascending colon; so that the usual medical treatment of enteroptosis, by application of adhesive strapping or special belt or corset, together with diet to increase the intra-abdominal tension by the accumulation of fat, etc., would prove of no avail. Advanced cases of chronic stenosis of the intestine could usually be diagnosed without the aid of the *x*-ray, but, nevertheless, it should be employed on account of its confirmatory evidence. For the early and positive diagnosis of adhesions producing constipation it was of great value. In the etiological classification of chronic constipation was that due to disturbances of the motor functions of the intestine, and this was subdivided into constipation due to retarded intestinal peristalsis, atonic constipation, and constipation due to enterospasm—spastic constipation. The great prevalence of constipation among women was well known, and Meynert, in his gynecological clinic, had found that 80 per cent. of the patients suffered from enteroptosis. In cases of this kind the musculature of the stomach and intestines and the muscles of the abdominal walls also were relaxed, and this was a factor likewise in the production of atonic constipation. The stigmata of typical cases of enteroptosis were readily recognized at sight, but many of the milder cases were apt to be either overlooked by the general practitioner or diagnosticated as nephroptosis alone, or possibly as simply "atonic constipation." The more moderate types of angulation from enteroptosis, the speaker believed, had a bearing on the disturbances in intestinal motility resulting in the symptoms of so-called atonic constipation. Frequently the *x*-rays had readily demonstrated the angulation to the satisfaction of the patient, and correcion of the enteroptosis had relieved or cured the constipation. It was a well-known fact that perigastric adhesions interfered with the motility and disturbed the secretion of the stomach, and, in his opinion, adhesions not sufficient in degree to produce stenosis of the intestines were often a cause of disturbance of the motor and secretory functions of the latter. In effect, therefore, careful investigations would demonstrate that, in the etiology of quite a large percentage of cases of so-called atonic constipation, enteroptosis with moderate angulations, or slight adhesions, were factors. He believed, furthermore, that intestinal adhesions with narrowing of the lumen and enteroptosis with marked angulations were frequent factors in the production of so-called spastic constipation, and in such conditions he had observed the typical symptoms of this, with the evacuation of small balls (groat feces) or pencil-shaped material. The spastic type of constipation was met with in those cases where the adhesions or the angulations from enteroptosis were of more pronounced degree than those observed with atonic constipation. These varieties of constipation every practising physician was liable to meet with, and he thought that all cases of chronic constipation should be carefully studied with the *x*-rays. He then cited a number of illustrative cases. In case 1 the *x*-ray showed a stomach with a long vertical limb and a short horizontal limb, at the level of the umbilicus—a "water trough" stomach. The transverse colon dipped below the umbilicus. The caput coli and ascending colon were much dilated and there was marked angulation at the junction of the descending limb of the descending transverse colon and its transverse limb; accounting for the dilatation. Indicanuria, nervous symptoms, and constipation persisted, in spite of mechanical support, electricity and the usual medical treatment. Operation (short-circuiting the intestine by the juncture of the ileum to the descending colon) was advised, but up to the present time this had been refused. In case 2 there was moderate gastroptosis, nephroptosis (right kidney, third degree), and the appendix was slightly sensitive. The sigmoid flexure was prolapsed and the rectum showed a tendency to prolapse. The radiograph confirmed the diagnosis. The caput coli was narrow and low in position, the splenic flexure high, and the transverse colon below the level of the umbilicis. The patient had greatly improved under medical treatment and repeated application of Rose's belt, and the tenderness at the appendix had disappeared. In case 3, that of an unmarried lady of 49, the ovaries had been removed in 1889 and the appendix in 1901. After the last operation pain and tenderness in the region of the stump of the appendix, together with marked constipation, developed. Dr. Kemp first saw her at Williamstown, Mass., in 1910, when the physical examination showed moderate tenderness in the right iliac region and enteroptosis. Adhesions were also diagnosticated, but there were facilities for an *x*-ray examination. The patient would not consider operation, and mechanical and medical treatment afforded partial relief. In New York Dr. Kemp examined the case again, in February, 1913, when the same diagnosis was made—enteroptosis with adhesions at the site of the appendix operation. The radiograph confirmed the diagnosis of enteroptosis, though it did not show the adhesions, and also revealed an angulation at the hepatic flexure, a second angulation where the descending arm of the transverse colon passed downward into the pelvis, and still another where the ascending arm first came in contact with the descending colon. Operation was still refused. Three other cases were described in the paper. In one of these there was obstinate constipation and a history of attacks of peritonitis. Physical examination showed narrowing at the sigmoido-rectal junction, which was regarded as probably due to adhesions. The radiograph showed marked adhesions about the transverse colon, considerable dilatation of the caput coli, and slight adhesions at the sigmoido-rectal junction. A laparotomy by Dr. Parker Syms confirmed the diagnosis, and the adhesions were severed. The patient did well for some months, when there was a recurrence of the constipation, and a radiograph taken at this time showed the presence of adhesions at the transverse colon. Dr. Syms again operated and marked adhesions were found, not only to the transverse colon, but also to

the ascending colon and between several coils of the small intestine and the abdominal wall on the left side. The adhesions were separated, as far as possible, and after this the constipation again improved. There were many interesting features in these cases, the speaker went on to say. Abnormalities in gastric secretion when there was enteroptosis he believed to be due to the misplacement of the stomach, and in his book on gastrointestinal diseases he had reported the disappearance of hyperchlorhydria after repeated application of Rose's belt alone. In cases with intestinal adhesions functional disturbances were, no doubt, in most instances, a reflex from these, just as such reflexes resulted from disease of the appendix or gall-bladder. Many cases of so-called atonic constipation he imputed to moderate intestinal angulations from enteroptosis or to slight adhesions, while more marked angulations or adhesions might produce the symptoms of spastic constipation. Unquestionably, correction of an enteroptosis uncomplicated by adhesions by such means as belts, adhesive strapping, corsets, and the increasing of abdominal fat would do much for the constipation in some instances, but cases of enteroptosis which could not be relieved by such means, including all those due to adhesions, belonged to the domain of surgery. Regarding the question of surgery, Dr. Kemp said he desired to present some problems for discussion, and, first, as to adhesions. In two of his cases, which were operated on for these, by skillful surgeons, the adhesions formed again, necessitating a second operation in each instance. In such cases, therefore, would it not be preferable to short-circuit the intestine by entero-enterostomy, and leave the intestines undisturbed? In that case what probability would there be of torsion of the gut or of some other portion of the intestine slipping beneath the adhesions, or becoming adherent to them? Second. In the cases of enteroptosis with marked angulations there was always great redundancy of the transverse colon, and suspension of the intestine would in some cases seem impracticable, and revision of the recoti muscles equally so. Would a double entero-enterostomy, thus short-circuiting the angulations, be preferable? In one of his cases, even if this procedure were carried out, there would still remain the sigmoid flexure, lying completely prolapsed in the pelvis and angulated. The additional problem would then remain, whether to resect, to short circuit, or to suspend the sigmoid. Unless some such procedure were adopted there would probably be still sufficient mechanical obstruction to cause constipation. In conclusion, he stated that it had been his endeavor, in this paper, to demonstrate not only the great value, but also the necessity of careful examination of all cases of chronic constipation by means of the Röentgen rays.

Some Radiographs of Obscure Stomach and Intestinal Cases.—Dr. Sinclair Tousey read this paper. For *x*-ray diagnosis in these cases, he said, the patient, as was well known, came with the stomach and intestine empty. A meal consisting of mashed potato, a glass of water, and an ounce or more of bismuth oxychloride formed an accurate mold of the stomach and cast such a dense shadow in the radiograph as to show the size, shape, and position of that organ. Dislocation, ptosis, and hour-glass contraction were evident at a glance, as seen in some of the radiographs shown. Having referred to the radiographing of other stomach conditions, he mentioned that the best demonstration of lesions of the rectum, sigmoid flexure, descending, transverse, and ascending colon, and cecum was by a radiograph made after a bismuth or barium enema. A number of the radiographs he had taken had been shown by Dr. Kemp. He then went on to say that the dangerous tendencies in recent *x*-ray work upon the gastrointestinal tract lay chiefly in the use of the fluoroscope and in the making of multiple radiographs of the same patient. It was very far from being true that any ray giving a perceptible fluoroscopic image through the abdomen could be applied indefinitely with safety. He did not permit this kind of work at all in his laboratory, but if he did so it would be only on condition that the dosage of the radiance used for fluoroscopy should be measured, and the safe time of exposure determined beforehand and strict account kept of every second's exposure. Another dangerous use of the fluoroscope lay in the making of a preliminary observation to facilitate the location of the patient, the *x*-ray tube, and the plate, in the effort to secure the picture of the desired parts upon a plate of rather small size, as 8 x 10 inches. The objection to multiple radiographs, and especially cinematographs, was the danger of over-exposure. Just as there had been a very distinct limitation to the number of pictures which could be safely made through the abdomen with the long, weak exposures formerly employed, there was about the same safely limit with the short, strong exposures of today. Because it was easy to give the exposures in rapid succession there was danger that the safe dose might be exceeded. From two to ten times as many pictures could be made with safety when an intensifying screen was made use of as when it was not; but when it came to a matter of twenty, thirty, or forty pictures, as in radiocinematography, one was dealing with a dose which should be exactly measured, and its effect upon the individual patient most carefully considered, before applying it. The modern apparatus made it possible to make individual pictures of moving organs, like the stomach, and this might be repeated at different stages of digestion; but Dr. Tousey thought it dangerous to make a very large number of exposures to show the actual motions of the organs.

Dr. Parker Syms said that this subject was still in its infancy so far as our actual knowledge went. He was, however, a great believer in infection as a causative factor. The peritoneum was able to take care of a good deal of infectious material, but, nevertheless, in doing so was exposed to considerable danger. There were some cases in which the adhesions were progressive. Radiographs were an aid to diagnosis, and in the case referred to by Dr. Kemp in which he (Dr. Syms) had operated, the *x*-ray did locate the angulation of the colon at the splenic flexure. This was a well-formed adhesion angulation, and when the adhesions were released immediate relief resulted; the patient becoming free from all distressing symptoms. After some months, however, there was a recurrence of the trouble. The adhesions formed again, and were particularly dense over the ascending colon. He had then operated a second time, and with favorable results, and he now hoped that the relief would be permanent.. There were some cases in which permanent relief could not be afforded by operating on the adhesions, and in these, after one or two failures, we now resorted to short-circuiting the colon. As to the *x*-ray, he thought it would be a great advantage if all the radiographs were taken by one man; so that we might have a single, uniform method to depend upon. The speaker then referred to a case in which radiography did not prove of much service. The patient was a neurotic, hysterical woman who had been in a number of hospitals. She weighed only 97 pounds and had vomited after every meal for four years. On operating he found that the source of her trouble was the obstruction caused by a band of adhesions just below the outlet of the stomach which lifted up the duodenum, and which the radiograph had not shown. Up to the present time the patient had had absolute relief.

Dr. Morris said that his experience had been like that of Dr. Syms. There was recurrence of adhesions because the original cause, a chronic toxic infection, remained. For this reason he had given up operating for adhesions, except for the relief of urgent symptoms. Worse adhesions sometimes formed than those previously existing. The logical conclusion was that it was better to remove the colon. This, however, was a pretty severe measure, and at present surgeons were adopting a procedure which, while of little severity, was at the same time effective. The latter was a short-circuiting of the colon, an operation which had been so simplified that it took but little time and gave the patient a minimum of inconvenience. Now, if we were able to prevent the reversal of peristalsis this would prove all that could be desired in quite a large number of cases. Methods were at present being tried out by surgeons, with the intention of preventing this reversal, which had a tendency to carry the bowl content back into the colon above the short-circuit gate.

Dr. A. Ernest Gallant said it seemed to him most unfortunate that the trend of the papers and discussion this evening should have been so strongly surgical, and that an impression of such a character should emanate from the meeting. He was convinced that the vast majority of these cases could be satisfactorily treated by means of mechanical support, though it was, of course, essential that such support should be of proper character and intelligently applied. He did not believe that one case in a thousand, if even as many as that, called for operation. This craze for surgical interference in such cases, he thought, however, was only a temporary one, which would run its course and pass away like the promiscuous fixation of loose kidneys in vogue a little while ago. In the doing away with that he was happy to say he had been a pioneer.

Dr. G. Reese Satterlee agreed with Dr. Syms as to the need of uniformity in bismuth radiography of the intestinal tract. The use of different amounts and kinds of foods and metals in a series of cases was misleading. In quite a large number of series of cases during the past two and a half years he had studied the motility of the intestinal

tract by means of the bismuth ray. Two leading points of interest were constipation and ptosis, with or without adhesions. For the ptosis the treatment might be either medical or surgical. Abdominal support would often suffice, but operation was sometimes necessary. Of the operative procedures, colopexy had been attended with success in his hands. In twelve cases it had been done with some good results as to constipation, and three of them had been followed long enough to show that relief had been accomplished. This might be slow, as in one patient with an eight-day constipation, in whose case, after eight months' unsuccessful medical treatment, colopexy eventually relieved the situation. He thought this operation might also be effective in the case of adhesions, by drawing the bowel out of the pelvis, where infective processes were apt to spread over a crowded bowel. He was now trying another method of overcoming adhesions, namely, by immunizing by means of autogenous vaccines made from bacteria isolated from the feces. This had proved successful in one case of obstinate ulcerative colitis of ten years' standing, relieving the toxemia. It seemed as if this method ought to have a promising future for the peritoneal infections.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OKLAHOMA STATE BOARD OF MEDICAL EXAMINERS.

April, 1913.

ANATOMY.

1. Give the origin and distribution of ulnar nerve.
2. Describe the sternum.
3. Locate saphenous opening and name an important vessel passing through it.
4. In disease of upper chest why is there frequently pain on inside of upper arm and about the shoulder?
5. How do the ventricles of the brain communicate with each other and with the subdural space?
6. Give a rule for locating the fissure of Rolando.
7. Name the arteries supplying intestinal tract from pylorus to anus.
8. Describe arrangement of gray and white matter in spinal cord.
9. Describe method of division and termination of capillary bronchial tubes.
10. Name a racemose gland. Describe its structure.

PHYSIOLOGY.

1. Define physiology.
2. Tell the functions of the third, fourth, and fifth cranial nerves.
3. What is the function of the uterus?
4. What is the function of the portal vein? What veins form it?
5. What is an enzyme?
6. Describe reflex action.
7. What is the function of the lymphatic system?
8. Tell the distribution and function of the pudic nerve.
9. Describe the cardiac cycle.
10. What nerves form the solar plexus?

CHEMISTRY.

1. Give the antidote for carbolic acid. For formaldehyde.
2. Give the chemical composition of iodoform.
3. How does permanganate of potassium act as a disinfectant?
4. What is the toxic agent in ptomains?
5. What is the formula of sulphuric acid?
6. Give the method of uranalysis for albumin and sugar.
7. Would you use iodine on the skin after a mercuric solution?
8. What is the law of Avogadro?
9. What is the antidote for arsenic?
10. What is chemistry?

MATERIA MEDICA AND THERAPEUTICS.

1. State the sources and dose of salicylic acid.
2. Describe the therapeutic uses of glycerin.
3. Name four principal coal-tar derivatives and give physiological action.
4. Name the principal potassium salts. Give dose and use of each.
5. Name three vegetable and three mineral astringents with dose of each.

Treat the following diseases, giving doses of drugs used, their therapeutic effect, diet, and prognosis.

6. Typhoid fever.
7. Pneumonia.
8. Pellagra.
9. Cerebrospinal meningitis.
10. Scarlet fever.

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. Describe how subcutaneous wounds may be produced. How many kinds of open wounds? Name them according to the way they are produced.
2. How does electricity produce death?
3. Give some of the conditions simulating death.
4. Name some peculiarities of some of the special senses which would furnish important evidence in relation to identity.
5. Give some of the symptoms of organic nervous diseases.
6. How does chloral hydrate produce death? Name lethal dose.
7. How does chloroform produce death?
8. What are the important symptoms of poisoning by digitalis?
9. By what method of examination would you ascertain that a person was suffering from a fatal dose of quinine?
10. How does antipyrine produce death?

PHYSICAL DIAGNOSIS.

1. Describe the general method of palpation.
2. In what condition should the examiner's hands be before applying them?
3. What regions are studied by a simultaneous application of both hands?
4. What condition may cause total abolition of fremitus?
5. Where is palpation of vocal fremitus of most practical value?
6. What does splashing fremitus signify when felt against the thoracic wall, shaking the body?
7. How many attributes of percussion sounds? name them?
8. Describe artificial vocal resonance (plegophonia).
9. Describe Broadbent's sign in inspection.
10. What is learned by percussion when we have simultaneous extension of the area of cardiac dullness toward both sides and upward of the pericardial sac?

BACTERIOLOGY AND PATHOLOGY.

1. What is acute miliary tuberculosis, and name three varieties of tubercle?
2. Name the lesions usually found in the second and third stages of syphilis.
3. What is hypertrophy of the heart? Give three causes for same.
4. How would you diagnose croupous pneumonia from catarrhal pneumonia by microscopic examination?
5. Name three ways by which you can determine whether a certain organism is or is not pathogenic.
6. How would you make a bacteriological examination of water suspected of fecal contamination?
7. Name a simple method of producing a pure culture of the typhoid bacillus.
8. Name three malarial parasites and the kind of malaria caused by each parasite.
9. Name three pathological changes that may result from cerebral hemorrhage.
10. Name three pathological changes that take place in peritonitis.

ANSWERS.

ANATOMY.

1. The *ulnar nerve* takes its origin in the inner cord of the brachial plexus. It is distributed to the elbow and wrist joints; to the Flexor carpi ulnaris and the inner half of the Flexor profundus digitorum; to the skin of the ulnar half of the back of the hand, and to the skin of the little finger and adjoining half of the ring finger on the palm of the hand.

2. The STERNUM is a flat, narrow bone, situated in the median line of the front of the thorax. It consists of three portions: Manubrium, gladiolus, and ensiform. It is about seven inches long. At the junction of the first two pieces is the angle of Ludovic; and here the second costal cartilage joins the bone. It articulates with the clavicle and seven costal cartilages on each side. Muscles attached are: Pectoralis major, sternomastoid, sternohyoid, sternothyroid, diaphragm, triangularis sterni, and aponeuroses of external oblique, internal oblique, rectus abdominis, and transversalis.

3. The *saphenous opening* is located on the anterior sur-

face of the thigh, at the upper and inner part, just below Poupart's ligament, and beneath the superficial fascia. It transmits the internal saphenous vein.

4. In disease of the upper part of the chest, the pain which may be felt on the inside of the upper arm and about the shoulder, is due to involvement of the supraclavicular branches of the cervical plexus, and the lesser internal cutaneous and intercostohumeral nerves of the brachial plexus.

5. The lateral ventricles of the brain communicate with the third ventricle by means of the foramen of Monro; from the third ventricle the aqueduct of Sylvius leads to the fourth ventricle; communication between the latter and the subdural space may occur through the foramen of Magendie.

6. To *locate the fissure of Rolando:* Draw a straight line over the top of the scalp from the inion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of three and one-half inches. This line will represent the location of the *fissure of Rolando.*

7. The *duodenum* is supplied by the pyloric, pancreaticoduodenal, and inferior pancreaticoduodenal; the *jejunum* and *ileum* are supplied by the branches of the superior mesenteric; the *cecum,* by the ileocolic and right colic; the *ascending colon,* by the right colic; the *transverse colon,* by the middle colic; the *descending colon,* by the left colic; the *sigmoid flexure,* by the sigmoid branches of the inferior mesenteric; the *rectum,* by the superior, middle, and inferior hemorrhoidal arteries.

8. In the spinal cord, the white matter is situated externally to the gray matter; the latter, on transverse section of the cord, is found in the center of the cord, and appears as two crescentic masses united together by a narrow, central, transverse band. Each of these crescentic masses has an anterior horn and a posterior horn.

9. "On entering a lobule, the small bronchial tube divides and subdivides; its walls at the same time become thinner and thinner, until at length they are formed only of a thin membrane of areolar, muscular, and elastic tissue, lined by a layer of pavement epithelium not provided with cilia. At the same time they are altered in shape; each of the minute terminal branches widens out funnel-wise, and its walls are pouched out irregularly into small saccular dilatations, called air-sacs. Such a funnel-shaped terminal branch of the bronchial tube, with its group of pouches, or air-sacs, is called an infundibulum, and the irregular oblong space in its center, with which the air-sacs communicate, an interceilular passage." (Kirkes' *Physiology.*)

10. "The mammary glands are compound racemose glands, and consist of gland-tissue which is made up of lobes, and these again of lobules. The lobes are connected by fibrous tissue, and between them is fat. Each lobule is composed of sacculated alveoli and a duct, the lobular duct. The lobular ducts discharge into larger ducts, which in turn discharge into a lactiferous duct, which may be regarded as the excretory duct of a lobe. Of these ducts, there are from fifteen to twenty; and they open at the surface of the nipple. Under the areola the tubuli lactiferi are dilated, forming ampullæ, in which, during the period of lactation, the milk accumulates in the intervals of nursing. The walls of the alveoli consist of a basement membrane, covered, during the period when the gland is not active, by a single layer of flat or cuboidal cells with one nucleus and presenting a granular appearance." (Raymond's *Physiology.*)

PHYSIOLOGY.

1. *Physiology* is that branch of science which treats of the functions of the organs and tissues of the body in a state of health.

2. The *third cranial nerve* supplies motion to the following muscles of the eye: Superior rectus, inferior rectus, internal rectus, inferior oblique, and levator palpebræ superioris. The *fourth cranial nerve* supplies the superior oblique muscle of the eye. The *fifth cranial nerve* has three subdivisions. The *first,* or *ophthalmic:* sensory to anterior half of scalp, conjunctiva and skin of upper eyelid, cornea, skin of nose, mucous membrane of nose, lachrymal gland. *Second,* or *superior maxillary;* sensory to conjunctiva and skin of lower eyelid, nose, cheek, upper lip, palate, upper teeth, and alveolar processes. *Third,* or *inferior maxillary;* sensory to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower lip, teeth, and alveolar processes of lower jaw. It is also motor to the muscles of mastication (temporal, masseter, two pterygoids), mylohyoid, and anterior belly of the digastric.

3. The function of the uterus is to receive the fecundated ovum, to retain it until it is developed into a mature fetus, and then to expel it.

4. The function of the portal vein is to carry the blood (with products of digestion and absorption) from the spleen, stomach, small intestine, pancreas, and large intestine to the liver. The portal vein is formed by the gastric, cystic, splenic, superior mesenteric, and inferior mesenteric veins.

5. Enzymes are more or less hypothetical substances, produced by living cells and capable of causing definite chemical changes in the media in which they develop.

6. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc,* which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

7. The function of the lymphatic system is to provide for the manufacture and circulation of the lymph, which provides the tissue cells with nutritive material and carries away their waste products.

8. The pudic nerve is distributed to the perineum, anus, and genitals; it is motor and sensory.

9. *The cardiac cycle* includes all the changes which occur between the commencement of one heart-beat and the commencement of the next; it consists of the alternate contractions (or systole) and relaxations (or diastole) of the auricles and ventricles of the heart. The contraction of the two auricles takes place simultaneously and is followed by the simultaneous contraction of the two ventricles; then follows a period during which the whole heart is in a state of diastole. The cycle then begins again with the auricular systole.

10. "The *solar plexus* is composed of three elements: the *celiac plexus* surrounding the origin of the celiac axis between the crura of the diaphragm and two *semilunar ganglia,* each lying on the corresponding crus of the diaphragm, and overlapped by the suprarenal capsule, and on the right side by the inferior vena cava. The plexus is continuous with subordinate plexuses, diaphragmatic, suprarenal, renal, superior mesenteric and aortic; and by means of *the hypogastric nerves* the aortic plexus becomes continued into the *hypogastric plexus,* which again forms the chief origin of the *pelvic plexuses.*" (Cunningham's *Anatomy.*)

CHEMISTRY.

1. *Antidote for carbolic acid.* Sodium sulphate, or alcohol; for *formaldehyde,* ammonia.

2. Iodoform is triodomethane, CHI_3.

3. Potassium permanganate is a powerful oxidizing agent, and its action as a disinfectant is due to the oxidation of the organic matter with which it comes in contact.

4. The poisonous agent in ptomaines is a *toxin.*

5. The formula of sulphuric acid is H_2SO_4.

6. To examine for *albumin:* The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent it is to be treated with a few drops of magnesia mixture, and again filtered.

"The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of nitric acid."

To examine for sugar: First remove any albumin that may be present, then "render the liquid strongly alkaline by addition of sodium carbonate. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color."

7. Iodine with a solution of mercurous chloride will produce a mixture of mercuric chloride and mercuric

iodide. For this reason I would not use iodine on the skin after a mercuric solution.

8. *Law of Avogadro:* Equal volumes of all gases, under like conditions of temperature and pressure, contain equal numbers of molecules.

9. The antidote for arsenic is freshly prepared solution of ferric hydroxide.

10. *Chemistry* is that branch of science which treats of the composition of substances, the changes they can undergo, and the laws governing these changes.

MATERIA MEDICA AND THERAPEUTICS.

1. SALICYLIC ACID. *Sources:* Oil of wintergreen; and made synthetically by combination of sodium carbonate and carbon dioxide, this is then treated with hydrochloric acid. *Dose,* 7½ grains.

2. *Glycerin* is used as an emollient, as a laxative, as a vehicle for other medicines; it has also been given in cases of hepatic and nephritic calculi.

3. *Four coal-tar derivatives:* Acetanilide, phenacetine, antipyrine, and lactophenine.

Physiological action of coal-tar derivatives: They reduce body temperature; they have an analgesic action; they depress the nervous system; they destroy red blood corpuscles and produce other changes in the blood; they have an irritant and toxic action on protoplasm.

4. The *potassium salts, with doses,* are: The acetate, gr. xxx; bicarbonate, gr. xxx; bitartrate, gr. xxx; bromide, gr. xv; carbonate, gr. xv; chlorate, gr. iv; citrate, gr. xv; effervescent citrate, gr. lx; cyanide, gr. 1/5; dichromate, gr. 1/5; ferrocyanide, gr. vij; hypophosphite, gr. vij; iodide, gr. vij; nitrate, gr. vij; permanganate, gr. j; sulphate, gr. xxx; and potassium and sodium tartrate, 5ij.

Uses: The bicarbonate and carbonate are gastric sedatives; the acetate, citrate, and effervescent citrate are diuretics and diaphoretics, and are also used in cases of gout, uric acid diathesis and scurvy; the sulphate and bitartrate are purgatives, the latter being also a diuretic and diaphoretic; the nitrate is used in asthma and is a diuretic and diaphoretic; the chlorate is used in tonsilitis, stomatitis, and pharyngitis.

5. *Three vegetable astringents:* Belladonna, gr. j; opium, gr. j; and hyoscyamus, gr. vij. *Three mineral astringents:* Alum, gr. xv; lead acetate, gr. ij; silver nitrate, gr. ½.

6. *Typhoid fever:* Rest in bed, liquid diet as a rule (chiefly milk, eggs, broth, etc.), intelligent nursing, cold sponging, brandy or strychnine sulphate, gr. 1/30; for collapse, calomel in divided doses gr. 1/10 for constipation, bismuth subnitrate, gr. xxx for diarrhea, turpentine stupe to abdomen for tympanites, morphine sulphate gr. ¼ for intestinal hemorrhage (also raise the foot of the bed), for perforation laparotomy is indicated. The prognosis is guardedly favorable; the mortality is about 5 to 8 per cent.

7. *Pneumonia:* Rest in bed, fresh air, nutritious and easily digested diet, vensection sometimes, calomel in divided doses gr. 1/10 to clear out the intestinal tract, strychnine sulphate gr. 1/40 as a cardiac stimulant, digitalis gr. j if the pulse is of low tension, if pulse is of high tension nitroglycerin gr. 1/100 with aromatic spirit of ammonia 5j, cool sponging with water or alcohol for the fever, for dyspnea and pain cardiac stimulants (strychnine) and morphine sulphate gr. ¼ are indicated, Dover's powder for the cough, sulphonal gr. xv for insomnia. Prognosis is uncertain; mortality is about 20 to 40 per cent.

8. *Pellagra:* Since the etiology is uncertain treatment is symptomatic; liberal diet, hygienic surroundings, and change of climate are beneficial; arsenic in the form of Fowler's solution or atoxyl (hypodermic of 20 drops of a 10 per cent. solution every third day) is useful. Mortality is from 5 to 25 per cent.

9. *Cerebrospinal meningitis:* Rest in bed, liquid diet, ice-bags to the head, and counterirritation to the back are essential. Morphine sulphate or chloral hydrate (dosage according to the age of the child) may relieve the restlessness and nain. Calomel in divided doses may be given to open the bowels. Lumbar puncture and laminectomy are sometimes necessary. Serum treatment is also employed. Prognosis is bad; the mortality is from 20 to 75 per cent.

10. *Scarlet fever:* Isolation, rest in bed, and liquid diet are essential, good ventilation and proper antiseptic precautions should be insisted on; the nose and throat may be cleaned with Dobell's solution; calomel in divided doses, for the bowels, and aromatic spirit of ammonia (mχ-x) or strychnine sulphate gr. 1/60 for the heart, cold sponging for the fever, and inunction with vaselin or cacao butter are the chief indications. Prognosis is guardedly favorable; complications are to be averted.

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. *Subcutaneous wounds* may be caused by falls, blows, crushes, or squeezes.

Open wounds may be incised, punctured, contused, lacerated, gunshot or poisoned.

2. The *causes of death by electricity* are thus summarized by Cunningham: "(1) Industrial electric currents which traverse the whole body transversely or longitudinally in sufficient intensity kill because fibrillary contraction of the heart is produced, and not, as has been hitherto surmised, by producing a total paralysis of that organ or by killing it outright. (2) Such currents neither kill the central nervous system outright nor paralyze it instantaneously. Death of the nervous system from such currents is due to the total anemia following a sudden arrest of the circulation. (3) In rare cases, when an electric current traverses only the cerebrocervical portion of the nervous system, in considerable intensity and for a considerable length of time, it may kill by asphyxia, consequent on a more or less complete inhibition of the respiratory movements which occurs chiefly during the passage of the current. No existing facts warrant the conclusion that the medullary respiratory center is paralyzed or killed in such conditions. (4) It may be possible for an electric current of enormous intensity and electromotive force to produce instantaneous death either by its disruptive action or by producing an instantaneous heat coagulation of the cellular constituents of the body. Industrial currents do not kill instantly, although, as a result of their action, death rapidly occurs." (Peterson and Haines' *Legal Medicine.)*

3. *Some conditions which simulate death:* Syncope, trance and catalepsy.

4. *Peculiarities of the special senses which have a bearing on identity:* Errors of refraction, color-blindness, imperfections in vision or hearing.

5. *Some symptoms of organic nervous diseases:* Paralysis, anesthesia or paresthesia, disturbance of reflexes, loss of control of bladder or rectum, pain, shock, atrophy or degeneration of any tissue or organ.

6. Choral hydrate probably produces death by failure of respiration; sometimes by pulmonary edema. *Lethal dose* depends on the age and habit of the victim; a dose of three grains has proved fatal to an infant, and a dose of over one ounce has been recovered from.

7. The cause of death in chloroform inhalation is uncertain; some attribute it to failure of the heart, others to failure of respiration.

8. *Important symptoms of poisoning by digitalis:* Nausea and occasionally vomiting. Sometimes colic and diarrhea. After two or three hours marked diminution in the frequency of the pulse, which may fall to 40 or even 25. Dyspnea, attended by a sense of oppression in the chest and coldness of the extremities. Headache, vertigo, and tendency to sleep. Usually attacks of syncope occur, provoked sometimes by the slightest movement of the patient.

9. An excessive dose of quinine will produce hyperemia of the ear and constriction of the vessels of the retina. The latter can be seen by ophthalmoscopic examination, the former by direct examination.

10. Antipyrine produces death, probably, by cardiac failure.

PHYSICAL DIAGNOSIS.

1. *Palpation:* "This method is employed by placing the hand upon and feeling the external surface of the chest. It detects tenderness, edema, vocal or tactile fremitus, and the amount of expansion. The back of the finger tips is frequently more sensitive than the palmar surface, and comparisons should be made at times during examinations. Fremitus is produced by the vibration of the air below the vocal cords, beginning in the bronchi, thence to lungs, and finally communicated to the cutaneous surface of the chest." *(Cyclopedia of Medicine and Surgery.)*

2. The examiner's hands should be clean, dry, and warm; and the nails should not be too long.

3. The anterior and lateral regions of the thorax.

4. *Vocal fremitus is absent* when air or fluid is present in the pleural cavity.

5. Over the anterior surface of the thorax.

6. Air or fluid in the pleural cavity.

7. *Percussion sounds are characterized,* as: Resonant, hyper-resonant, tympanitic, normal, dull, flat, cracked-pot, amphoric.

8. *Plegaphonia* is "tapping on the larynx or trachea, to take the place of the voice sounds in auscultation." (Stedman's *Medical Dictionary.*)

9. *Broadbent's sign* is a retraction of the left side and back adjacent to the eleventh and twelfth ribs observed in adherent pericardium.

10. Pericardial effusion.

BACTERIOLOGY AND PATHOLOGY.

1. *Acute miliary tuberculosis* is an infectious condition due to the presence of miliary tubercles (chiefly in the

lungs). *Three varieties of tubercle:* Gray, yellow, and conglomerate.

2. *The second stage of syphilis* is characterized by: Sore throat, mucous patches; the skin lesions or syphilides, which are characterized: By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical. In this stage may also appear: Iritis, periostitis, and alopecia.

The *third stage* is marked by: Anemia, gumma formation, periosteal nodes, headaches, endarteritis and various other diseases.

3. *Hypertrophy* of the heart is an overgrowth or increase in the muscular tissue which forms the wall of the heart. *Three causes:* Emphysema, Bright's disease, and prolonged muscular exertion.

4. In the sputum of croupous pneumonia the diplococcus pneumoniæ may be found; this is never present in catarrhal pneumonia.

5. To *prove that bacteria cause disease* it is essential: (1) That the microorganism be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal. These are called the rules or postulates of Koch.

6. The water should be carefully collected in sterilized bottles, and then examined for the colon bacillus. This latter grows on the ordinary media; stains readily with the ordinary anilin dyes, but not by Gram's method; and is motile, flagellated, non-chromogenic, non-liquefying and non-sporogenous.

7. *Pure culture of the typhoid bacillus.* "The bacillus is best secured in pure culture, either from an enlarged lymphatic gland or from the splenic pulp of a case of typhoid. To secure it in this way the autopsy should be made as soon after death as possible, lest the colon bacillus invade the tissue. No special precautions need be taken, as the bacilli are usually present in pure culture. Care must be taken, however, to plant the culture in bouillon containing glucose, and in milk in order that the absence of fermentation and coagulation may make sure that no colon bacilli are present." (Macfarland's *Bacteriology.)*

8. The plasmodium vivax causes the tertian variety; the plasmodium malariæ causes the quartan variety; and the plasmodium præcox causes the estivoautumnal variety.

9. Wasting of the paralyzed muscles, contractures, rigidity.

10. Adhesions, infection and pus formation, fatty degeneration.

(*To be concluded.*)

Therapeutic Hints.

Treatment of Impetigo of the Nostrils and of Vestibular Rhinitis.—G. Laurens states that impetigo of the anterior nares is very common in the child and is the result of a chronic rhinitis or of adenoid growths. It is characterized by the presence of crusts, with a chronic irritation and frequently a secondary lymphangitis of the upper lip. The treatment is the care of the general health, the removal of adenoids, irrigation of the nose with normal salt solution, and the application at night of the following ointment:

℞ Ichthyol, 1 gram.
Vaseline, 20 grams.

or

℞ Calomel, 0.25 gram.
Vaseline, 25 grams.

Vestibular rhinitis is characteried by the presence of crusts in the anterior nares, and frequently by the development of a true folliculitis, with the formation of pustules and sometimes of furuncles at the border of the nostrils. Painful fissures may be present. The most disagreeable complication of this condition is sycosis of the moustache region. The treatment is generally a protracted one. All underlying causes, such as blephritis and disease of the lacrymal tract, should be attended to. A rhinitis should be combated with saline irrigations. Hypertrophied turbinates should be corrected. At night the following ointment should be applied:

℞ Ichthyol,
Yellow oxide of mercury, of each, 0.50 gram.
Vaseline, 20 grams.

The following lotion should be used:

℞ Precipitated sulphur, 5 grams.
Alcohol (90 per cent.), 10 grams.
Water, 30 grams.

A 10 per cent. sulphur ointment is effective: Swabbing the parts daily with a 5 per cent. solution of nitrate of silver is of value in the scaly and non-purulent forms of vestibular rhinitis.

In suppurative folliculitis it is necessary to incise the lesions and to touch their base with 90 per cent. alcohol, and then with the following:

℞ Powdered saffron, 0.20 gram.
Camphor, 0.50 gram.
Zinc sulphate, 3 grams.
Copper sulphate, 1 gram.
Distilled filtered water, 100 grains.

This mixture is thoroughly shaken, allowed to stand for 24 hours, and then decanted.

CLINICS, DEPARTMENT OF PUBLIC CHARITIES

CALENDAR, OCTOBER 1913

MONDAYS

THE MODERN TREATMENT OF TABES.

By JOSEPH COLLINS, M.D.,

NEW YORK.

PHYSICIAN TO THE NEUROLOGICAL INSTITUTE OF NEW YORK.

The treatment of tabes, the most frequent organic disease of the central nervous system, is a subject that must interest the general practitioner, for in practically every instance he encounters the possessor of the disease long before the counsel of a neurologist is sought. If I may judge from what patients tell me, the treatment which they frequently receive at the hands of the general practitioner is not that which has the stamp of approval set upon it by those who have had much experience in the treatment of the disease. It is partly since the advent of salvarsan and neosalvarsan into the field of therapeutics that the approved treatment of tabes has been subject to material modification. Having now had nearly three years' experience with these preparations in the treatment of nervous diseases that flow out of syphilis, and especially having in this time treated upward of one hundred cases of locomotor ataxia with this substance or remedy, I am moved to set forth my experience in this direction, and, meanwhile, to discuss in its entirety the treatment of tabes.

The Cause of Tabes Is Syphilis.—I shall assume that it is generally admitted that tabes is a disease that flows from syphilis. Whether or not there are instances that occur in individuals who have not had this infection is a matter of personal experience and belief. My belief is that tabes is a syphilitic disease in every instance. There are many instances of sclerosis and decay of the posterior columns of the spinal cord which have a symptomatology, subjective and objective, resembling that of genuine tabes, but which flow from other causes than syphilis. But in every instance such cases can be distinguished from genuine tabes. The utilization of the Wassermann test of the blood serum and of the cerebrospinal fluid has had much to do with convincing those who have opposed the unity of causation of tabes. The general acceptance of the belief that a cerebrospinal fluid which in addition to giving a positive Wassermann contains an excess of lymphocytes (more than ten to the cubic millimeter), an excess of globulin, and which reduces Fehling's solution, indicates the existence of the syphilitic virus in a state of activity within the system, now permits us to take a far more dogmatic statement of the luetic origin of tabes than was formerly justified. We know, to be sure, that the Wassermann test is positive in other states of disordered health, which are by no means syphilitic in their origin; we know also that a lymphocytosis may result from pathological states that do not have their origin in this disease; but despite this, the occurrence, clinically, of symptoms which we know from experience are indicative of tabes, plus the occurrence of this information furnished by the laboratory, is conclusive.

Since the time when we began to avail ourselves of the corroborative information to be obtained by the application of laboratory methods in this disease, we have learned that cerebrospinal fluid taken from patients with tabes varies in its constituents and in its reactions, especially does it vary with the different stages of the disease and with intensity of the disease and with the kind and amount of treatment to which the patient is subject. For instance, in the early stage of the disease, that is, in the stage that corresponds clinically with the occurrence of sensory symptoms (paresthesias, pain, easily induced fatigue, indefinite vesical symptoms), and especially in those cases in which the symptoms have come on with considerable abruptness not long after the original infection (within five years), a stage which I believe is dependent largely upon meningeal involvement, the lymphocytosis is profound, often reaching over one hundred cells to the cubic millimeter, the globulin content is greatly in excess, and the Wassermann reaction is strongly positive, whereas in cases that have been in existence a long time and especially those that have developed slowly and subject to more or less mercurial treatment, the condition of the cerebrospinal fluid is very different.

The significance of the lymphocytes in the cerebrospinal fluid taken from patients with syphilis of the cerebronervous system is not known. It is thought by some that the number of cells stands in direct relationship to the activity of the underlying pathological process, and the fact that they diminish and disappear while the patient is given remedies that aim to cure the disease would tend to support this view, but despite this, the opinion is not yet acceptable. It is no uncommon experience to find the lymphocytes increased after one or a few injections of salvarsan or mercury. To be sure, the increase is usually temporary and the permanent effect of such treatment is always reduction.

The treatment of tabes may be discussed under three headings:

1. *Causal Therapy.*—Treatment directed against the cause of the disease, *i.e.* syphilis, and the pathological state which it causes in the spinal cord, the meninges, the ganglia of the spinal cord and the posterior roots.

2. *Symptomatic Therapy.*—Treatment undertaken for the relief of the symptoms of the disease—pain, paresthesias, sphincter incompetency, ataxia, hypotonia, arthropathy, diplopia, optic atrophy, etc.

3. *Plan of Treatment.*—Attitude of the patient toward the disease, work, efficiency, happiness.

What Patients Afflicted with Tabes Should Be Subjects to Antisyphilitic Treatment, and What Are Our Reliable Antisyphilitic Agencies?—Every patient with symptoms of tabes whose cerebrospinal fluid shows on microscopic examination to contain ten or more lymphocytes to the cubic millimeter should be given vigorous antisyphilitic medication, providing no contraindication to such medication exists. The reliable antisyphilitic agencies which we are in possession of at the present time are mercury and salvarsan. They should be given simultaneously or sequentially and until every indication of the activity of the syphilitic virus within the system has ceased to exist; *i.e.* until it can no longer be detected by laboratory examination. Iodide of potassium is not in my experience an antisyphilitic agency, and it should never be used as a routine measure in the treatment of tabes. I have frequently dwelt upon what I believe to be the injuriousness of this drug in the treatment of tabes, but I regret to say that practically every patient that I see for the first time in advanced stages of the disease, and especially those that have had conspicuous eye symptoms which have caused them to seek counsel from ophthalmologists, have been so treated.

Which is the most potent antisyphilitic agency in the treatment of tabes—salvarsan or mercury? A satisfactory answer to this question cannot yet be given. The treatment of tabes is far more satisfactory now than it was before Ehrlich added salvarsan to the pharmacopeia. Salvarsan alone does not seem to bring about the degree of recovery that salvarsan plus mercury does. In some instances it is impossible to obtain and maintain a negative Wassermann reaction in the blood serum and the cerebrospinal fluid, and to bring about a normal globulin and cell content of the latter by administering salvarsan alone, no matter the dose or the frequency of administration. But when such administration is followed by mercury, conditions, approximating those of health, are quickly brought about. I have had far better results from the administration of salvarsan in the treatment of tabes than I have had from mercury. I have had better results from the use of both of them than from the use of one of them alone.

Salvarsan, that it shall be of real, lasting service in the treatment of tabes, must be given repeatedly. This is one of the most important lessons that we have so far learned concerning it. The interval between the first dose and the repetition of it should not be longer than from ten days to a fortnight. The third dose should be administered within the month and the fourth within a month after the third.

If neosalvarsan is used instead of salvarsan the interval betwen the administrations should be less. Neosalvarsan is given one dose (0.9 gm. for men, and 0.45 gm. for women) every third day for four doses, and then an interval of from six to eight weeks is allowed to transpire before the medication is resumed. During this time in many instances it is advisable to give mercury, possibly in large doses, or cacodylate of soda. We are assisted in determining whether we shall or shall not give mercury after salvarsan administration by the chemical and microscopical findings in the cerebrospinal fluid. For instance, if a patient who had the symptoms and signs of tabes and the characteristic blood and cerebrospinal findings of the disease should have, after the administration of one or more doses of salvarsan, what is called a negative condition in these fluids, then we would not be justified in giving further antisyphilitic medications. Indeed, before returning to it we should await what are called positive signs in the blood or in the fluid.

I have discussed at some length the mode of administering salvarsan to patients afflicted with syphilitic nervous diseases in an article written in conjunction with Dr. R. G. Armour and published in the *Journal of the American Medical Association*, June 22, 1912. The various reasons for preferring the intravenous method of administration are there set forth.

The Dangers of Salvarsan Medication.—Either the dangers of salvarsan administration have been exaggerated or we have been especially fortunate. We have had no serious results whatsoever in upward of 3,000 administrations, with one exception. In that case, a young woman who received a full dose developed the symptoms of a transverse myelitis, which disappeared at the end of four months. We have had three cases in which acute and severe symptoms of arsenical poisoning developed, such symptoms as papulomacular eruption, garlic odor to the breath, nausea and vomiting; symptoms of collapse came on within twenty-four hours after the administration of salvarsan. But all of these cases yielded very readily to the administration of alkali (carbonate of magnesium), high rectal irrigations, and hot baths. We have encountered no instance in which nephritis developed, and so long as the kidneys act normally there is very little danger from salvarsan intoxication. We have seen no instance in which any disorder of the optic nerve has developed, nor de we hesitate to administer it to patients who have disease of the optic nerve induced by syphilis.

The administration of salvarsan in no way tends to dislodge mercury as an adequate agency to combat syphilitic nervous disease.

Mercury should be given as an adjuvant to salvarsan. Not that it is not an adequate spirillocide—indeed it may be quite as potent in this direction as salvarsan—but when administered in sufficient doses to act efficiently as such, is a powerful depressant, and often causes serious disorder of nutrition (ptyalism, gingivitis, loss of teeth, digestive disturbance, emaciation). The most competent ways of administering it are by inunction and intramuscularly. My preference is for the latter method, and in the shape of the salicylate of mercury suspended in liquid albolene. I have had much experience with other preparations, and particularly with enusol (an arseniated salicylate of mercury) which, largely because of Erb's approbation, has had considerable vogue both here and abroad. I have discarded its use entirely. My experience in no way substantiates that of Schaffer of Budapest, Hudovernig, and others who have published statistics setting forth its value in the treatment of tabes. My experience with atoxyl and iodine convinced me of their worthlessness in the treatment of tabes.

The important point in the treatment of tabes by mercury is that it shall be administered in sufficient doses to influence the disease and to destroy its cause, and yet in the meantime not injure the patient. This point I have discussed in a previous article published in the MEDICAL RECORD of January 27, 1906, so I shall not take it up again here.

After	11	14	6	19	0	133	5	20

In order to show graphically the result of salvarsan medications upon the blood in cerebrospinal fluid, I have tabulated the results in the last twenty-five cases of tabes, many of which are still under treatment. Any one who will take the trouble to examine this table will see the effect that it has upon the Wassermann reaction both of the blood serum and of the cerebrospinal fluid. It likewise shows the very striking results which it has upon the cell content of the cerebrospinal fluid.

We have not entirely finished with the causal therapy of tabes when we have satisfactorily or fully discussed the treatment directed against the syphilitic virus. There are other agencies concerned in the causation—the precipitation one might better say—of the disease, and chief among these are agencies, influences or activities that exhaust the peripheral sensory neurons. Every experience that makes for great weariness, that tires the eyes, that puts stress upon the digestive tract or bladder; every influence that causes excessive radiation of bodily heat; in brief, the activity of any agency that depreciates the patient's vitality causes the disease to develop earlier and to progress more rapidly than it otherwise would, and the therapy that does not take this into consideration fails in an important feature.

There are many measures that we utilize in the treatment of tabes that are not directed so much against the cause of the disease, or the disease process, as they are against the inroads which the disease makes upon the patient's vitality. Among these are electricity, massage, hydriatic measures, cauterization, nerve stretching, diet, climatic consideration; medication and reeducation of purposeful movements. Two forms of electricity are useful in the treatment of tabes, galvanism and the high-frequency current. Neither of them has specific or great value despite what has been said by enthusiasts in their favor. Galvanism, the positive pole to the spinal column applied labile fashion, the negative pole over the sternum, a mild current flowing, will, after ten minutes' application, cause the back to have a lively red color; applied daily often has a beneficial effect subduing pain, both the lightning pains, and the "sore pains," and in producing a general tonic effect, that is, a feeling of well being, manifest particularly in improvement of paresthesiæ and motor weakness. Whether or not the application has a retarding influence on the pathological process, which is the foundation of the disease, we do not know. Empirically we know that patients feel better, oftentimes, as the result of this treatment. Static electricity given in the form of short sparks, with or without the insulating plate and in the form of the breeze, is often useful in overcoming the paresthesiæ of tabes and in stimulating the nutrition of the muscles, but it has no effect upon tabetic pain.

Of the mechanical measures, massage is by all means the most serviceable. Deep massage of the entire body, both kneading and grasping of the subcutaneous tissues and muscles, between the thumbs and fingers, is in the majority of instances grateful to the patient and followed, as a rule, by a feeling of increased static and locomotive security and capacity for relaxation. There are few patients with tabes in reality that are not benefited by massage judiciously and temperately administered. When it makes the patient nervous, fidgety or exhausted, its use should not be persisted in.

Nearly all patients with tabes are excessively, often painfully, sensitive to cold, and especially to the application of cold water. This makes it oftentimes difficult for us to avail ourselves of the usefulness of hydriatic procedures, and especially of the tonic douche bath and tonic half-bath. It is worth while, however, to persist in the use of these two most useful measures, for their tonic effect is greater than any other mechanical measure, and the reward of persistence is that the patient tolerates the treatment without discomfort. The salt rub, and flagellation with the end of a coarse towel taken dripping from cold water (65° F.) are useful measures to prepare the patient's skin for the tonic douche or half-bath, and they are themselves important adjuncts to any tonic treatment.

The dietetic and climatic treatment of tabes consists in the application of the principles of common sense. The wholesome diet that will nourish the patient and aid his vital forces to combat the infection that is causing his extremities, and climatic conditions that will permit him most easily and readily to follow the rules of hygiene, encompasses the matter. As a matter of fact, the diet for a tabetic depends in a large measure upon the state of his digestive organs and their juices. Not infrequently there exists hyperchlorhydria, rarely an achylia, and when such conditions exist they must be attacked both medicinally and dietetically. French writers have attempted to maintain that the arthritic diathesis (which means more apparently to them than to others) plays an important rôle in tabes, and that it must be combatted by a lacto-vegetarian diet. A mixed diet of food well prepared for digestion and easily assimilated is the diet for tabetics. Extremes of temperature, dampness and humidity depress and enervate sufferers from locomotor ataxia. When the patient's financial circumstances permit him to choose a climate these are the features to be avoided. To exchange the comforts and facilities for being cared for which

the patient's home provides for the discomforts of travel and the inadequacies of hotels, even though there is a gain in the way of climate, is unwise. On the other hand there is a clinical type of the disease, the one in which hypotonia is the conspicuous symptom, that is often much benefitted by change from home to a properly equipped sanitorium in a suitable climate. There is no drug that has any influence to arrest the sclerotic process that constitute the anatomical basis of the disease. Mercury and salvarsan may, and do sometimes, perhaps often, destroy the spirochetes, and then if degeneration has not proceeded too far restitution may result. Ergot, nitrate of silver, chloride of aluminum, belladona, and strychnine which have been lauded as efficient agencies to check the disease process are, I believe, valueless in the treatment of tabes. Iodide of potassium, which, I think it is safe to say, is given at one time or another in large doses to every individual suffering from this disease is, I maintain, of no use. Indeed, in very many instances, it is injurious, impairing the patient's vitality, disordering his digestion, depreciating his nutrition. I believe that the majority of neurologists are of this opinion, and that their teachings are in conformity with it. This being so my early experience is inexplicable, *e. g.*, a patient with tabes who bears witness that he has been under treatment with iodide of potassium frequently, as much as from two to three hundred grains a day.

There exists today in the rank and file of the medical profession an ineradicable belief that tabes is a "tertiary" manifestation of syphilis, and that iodide of potassium is a "specific" for "tertiary" manifestations. Therefore, iodide of potassium is given to tabetics. Mrs. Wharton's delineation is not the only "Custom of the Country." This is one, and until a new generation of physicians differently instructed in the temples and wards in which they first imbibe medical knowledge replaces the present one, it will remain so. Meanwhile, those who, like myself, are witnesses daily of the baneful effects of its administration, will continue to protest against its use whenever occasion offers. There are symptoms of tabes that demand mitigation or relief, and to ameliorate them is an important part of the physician's problem. These symptoms are pain and paresthesiæ, vesical and rectal incompetency, gastric and laryngeal crises, arthropathies and perforating ulcers, hypotonia and ataxia, ocular palsies, and insomnia.

The pains of tabes are sometimes relieved by coal-tar derivatives alone, in combination or administered simultaneously with some cardiac stimulant such as caffeine or alcohol. At other times nothing save opium will relieve them, especially if they are associated with symptoms called "crises," gastric, laryngeal, or vesical. No physician needs to be warned of the great danger of using morphine for the relief of tabetic pains. It relieves them, but its use is followed by a lessened capacity of resistance which manifests itself in clamor for repetition that few sufferers can resist, consequently the morphine habit is a not infrequent and disastrous result of its occasional use. As a rule sufficient relief from tabetic pain can be obtained by the administration of phenacetine, aspirin, acetanalid, or pyramidon to permit the patient to withstand it for the time. A full dose of castor oil, the application of the actual cautery lightly to the spine; prolonged hot baths are often efficacious, combined with suitable drug administration, in terminating an attack. Conformation to the rules of hygiene that have been found to apply to the victims of the disease will diminish both the frequency of the attacks and the intensity of the pain. Unquestionably deep massage, putting the spine upon the stretch (Sprimon's method), the application of the galvanic current to the spine and the avoidance of indigestion and fatigue diminish the likelihood of pain. What has been said regarding the amelioration of pain applies equally to the paresthesias of tabes, one of the distressing symptoms in some cases. Of all the agencies for the relief of this symptom none is more potent than light cauterization of the spine frequently repeated, a measure which, I regret to say, is often neglected for an inferior but more easily applied substitute, viz., sedative drugs.

For the relief of vesical incompetency there is a drug of some real value, belladona. It must be given in doses that cause so-called physiological effect. To counteract the pernicious results arising from decomposition of urine within the bladder urotropin is of undoubted value. But nothing succeeds so well in cases in which vesical incompetency is a symptom, that is practically in all cases of tabes, as putting the patient upon a time table for urinating. He should be advised to make a voluntary effort to void urine every four hours during the day, and to facilitate conformation to the order he should keep a "time sheet." Soon it becomes a habit and thus saves many a patient hours and days of misery. When the physician suspects that a tabetic patient retains a considerable amount of urine in the bladder after voluntary urination he should pass a catheter to determine how derelict the bladder really is, so that he may be better able to determine just what tonic measures, such as strychnine and static electricity, to use, and whether or not to administer urotropin.

The crises of tabes, gastric, laryngeal, and vesical, are so unbearable that they demand relief, and in many instances morphine alone administered in large doses will relieve them. Fortunately the danger of forming the habit is not so great as it is when administered for the relief of tabetic pain. In the first place crises are comparatively rare symptoms of tabes, and in the second place much can be accomplished in preventing their occurrence by constitutional and local treatment. Patients who have gastric crises should have their gastric juice investigated and abnormalities of it corrected by suitable chemical additions. As a rule an attack is best combated by administering a cathartic if it can be retained, or if not as copious an action of the bowels as is possible should be secured by enemata; by absolute cessation of attempt to feed the patient by the mouth, at least in the beginning of the attack; by stimulation of skin activity with hot packs, also a counterirritant attack; by the hypodermatic administration of pantopone (ampoules 1/6 to 1/3 gr.), and if this does not succeed then the administration of morphine (1/3 to ½ gr.). If the attack is protracted, resort must be had to nutrient enemata. It is the treatment during the interval between attacks that is most important, and such treatment is the general treatment of the disease. I have never encountered an instance of laryngeal crisis that demanded operative intervention, though I have seen one patient brought to the operating table. The patient is now and has been for four years a hard-working gardener. His at-

tack was combated with morphine and atropin, and his disease was brought to a standstill by salvarsan and mercury.

The arthropathies of tabes, Charcot joints they are commonly called, should be immobilized either in plaster, by braces or splints, and not manipulated, painted with iodine or otherwise irritated, while constitutional treatment is being given. Oftentimes, unfortunately, they develop in conjunction with profound hypotonia, when the problem of their treatment becomes more difficult. As a matter of fact hypotonia is the most difficult of all the symptoms of tabes to treat satisfactorily. It is the most important underlying cause of ataxia, and when it occurs in an advanced degree it is peculiarly rebellious to treatment. All the measures that are known to increase muscular tone from volitional movement to the administration of strychnine should be tried. The greatest benefit may confidently be expected from faithful adherence to the system of reeducation of movements purposeful, or voluntary movements known as the "Frankel System." It is astonishing the improvement that some patients with profound ataxia make who are given systematic instruction along the lines formulated particularly though not originated by Frankel of Heiden. In the Neurological Institute of New York, where such instruction is given as a routine measure to tabetics, I have seen results in the past four years which I had never been able to obtain for private patients, the reason being, in all likelihood, that I had not been able to carry them out systematically and continuously. The incentive to continue with them which the beginner has in seeing about him those who a few weeks or months before were obliged to walk with sticks or crutches, now walking unaided, is no small element of the success which attends the use of the system in institutions.

Of the early symptoms of tabes ocular palsies are the most distressing, unless the levator palpebræ is paralyzed so as to close the eye. The diplopia that results from paresis of the external rectus or the superior oblique, together with very slight involvement of the third nerve, bewilders the patient, and contributes profoundly to uncertainty of station and gait. Such ocular palsies are among the early symptoms of tabes, and not infrequently occur five or even ten years before any of the symptoms from which the diagnosis is readily made, appears. On consulting a physician, a specific history being obtained, they are given without exception large doses of iodide of potassium; and the physician who administers it concludes that because the diplopia mitigates, the medication is responsible for this result. In reality such diplopia ameliorates and disappears in practically every instance without medication. The diplopia and ocular palsies of early tabes are evanescent phenomena, unless the sequelæ of the paralysis is such as to cause permanent deformity. I have never seen an instance in which I was convinced that the administration of iodide of potassium had any beneficial effect in facilitating the rapidity with which ocular palsy disappears. On the other hand I have seen many cases in which I was convinced the underlying disease, namely tabes, had been influenced and developed more rapidly on account of the numerous doses of this drug which was given. For instance, at the present time, in the hospital we have a patient who for upward of three months was given between 500 and 800 gr. of iodide of potassium daily by the ophthalmologist whom he consulted for the relief of diplopia. The depreciatory effect of the drug upon his nutrition was not recovered from for a long time. The treatment of the tabetic ocular palsies is the treatment of the disease of which they are symptoms, and it consists in the appropriate use of salvarsan and mercury, and of the physical measures, the application of which make up the better plan of treatment of the disease. Meanwhile the patient's comfort is enhanced by wearing a shield which compels him to depend upon monocular vision. In certain rare instances in which the paralysis does not disappear it may be advisable to take into consideration advancement of the tendon of one or other muscles of the eye, but this should not be undertaken before the eyeball has assumed what may be considered to be a permanent position.

The most important factor of the treatment of tabes next to the administration of the substances that destroy the cause of the disease, one that is almost uniformly, and, as it were, studiously neglected, is the general nutrition of the patient. It cannot be expected that an individual will be able to withstand the onslaught of the spirochetes on a vital and vulnerable part of his system unless reparative forces of his nature or economy are enhanced. The chief value of such physical measures as the application of water, electricity, massage, exercise, etc., is the uplift that they give to the individual nutrition. In addition to these measures we have two which are not utilized as frequently as they should be. One is the cacodylate of soda and the other phosphate of soda. Aside from small doses of salvarsan I know of nothing that aids the patient to pick up so quickly as the former of these drugs. My mode of administration of it in the majority of instances is to follow the administration of a course of mercury hypodermatically with a course of these two drugs, giving them alternately for a period of from four to six weeks. The preparation that I use is cacodylate of soda, the dose being one ampoule, three-fourths of a grain, and a preparation known as soude vital. Aside from these I rarely administer any so-called tonic medication.

The Plan of Treatment.—Next in importance to the causal treatment of tabes, possibly indeed equalling it in importance, is the plan of treatment. Nothing does so much injury to the patient or his prospects of recovery as a pessemistic attitude on the part of the physician. "He (one of my assistants) said his spinal cord was dead and what could we expect," explained the wife of one of my patients, who was relating the experience of her husband in the two years that had elapsed since I first saw him. "So when they told him that he could be cured with goat serum we took him to Detroit." Then the chiropractitioners divorced him from the remainder of his savings, while he became reduced to crutches. Many patients with tabes live useful, active, efficient lives for years, and decades after the disease has become established. I could quote many examples both from history and from my own experience to substantiate this statement. The most brilliant exponent of English letters of the Victorian era had tabes for the last twenty-five to thirty years of his life. I have had for years under my observation and care the active head of an extensive railway who has had the disease for twenty years. Even a business which requires such peripatetic activity as the management of a baseball team is consistent with the possession of the disease.

In the vast majority of instances it is good judgment on the part of the physician to explain to the

patient fully, and in a way that will not alarm him, just what the disease is, that it need not materially shorten his life; that fifteen to twenty-five years of comparative efficiency may be vouchsafed him, and that vigorously combated a certain degree of functional preservation and restitution may be anticipated. It cannot be expected that every case of tabes will justify such prophecy. The majority will however. Those who have marked hypotonia respond most disappointingly to treatment. The amaurotic type, also unfortunately go on, so far as blindness is concerned, uninfluenced by treatment. But the algic and esthetic type and the type with early profound ataxia often respond most favorably to treatment. Few things have more unfavorable effect upon the disease and its possessor than lack of courage, improper point of view concerning his disease, and hopelessness.

On the other hand, nothing has a more beneficial effect upon the disease, save causal therapy, than a firmly rooted belief that a certain degree of efficiency and many years of usefulness may be vouchsafed the patient despite the possession of the disease.

37 West Fifty-fourth Street.

THE USE OF TUBERCULIN IN THE DIAGNOSIS OF OBSCURE CONDITIONS IN THE GENITOURINARY SYSTEM.*

By EDWIN BEER, M.D.,

NEW YORK.

The object of the following brief paper is to emphasize the importance of a very useful and very much neglected aid in the diagnosis of tuberculous conditions in the genitourinary tract. In the now vast literature of genitourinary tuberculosis there is very seldom even the slightest reference to the usefulness of diagnostic injections of "old tuberculin." In the masterly paper of Prof. Rovsing, read in June, 1912, at Atlantic City, he reviewed all the methods of diagnosis in renal tuberculosis, and much to my surprise failed to draw attention, either favorable or otherwise, to the use of tuberculin.

In view of these facts, and as I have found tuberculin of great assistance and have experienced no ill effects from its use, I determined to call attention once more to this diagnostic aid. To make this paper clear, I shall first refer to the evidence in favor of the specificity of the tuberculin reaction, and then I shall cite some illustrative obscure cases of renal, prostatic, and testicular diseases in which the tuberculin definitely assisted in making the diagnosis; thereafter I shall attempt to put together the experience of some others along these same lines.

Before beginning to cite experiences, let me say that I employ imported "alt tuberculin." This is diluted, so that five drops are equal to ½ milligram.*

*℞

Old Tuberculin	0.05
Trikresol	0.15
Distilled water qs. ad.	30.00 c.c.

S. ♏ V = 0.0005 old tuberculin.

This is kept on ice when not needed. Injections are made only in nonfebrile cases, the temperature being taken regularly every four hours for several days prior to the injection. Five minims is the initial diagnostic dose, and only in case of a negative reaction is a larger dose permissible. Under such conditions, the dose may be gradually increased, ½ milligram at a time, up to a maximum of 5 milligrams. In children a much smaller initial dose should be used (1/20 milligram). This increase should be gradual, allowing at least two to three days, preferably the latter, between injections. A positive and useful reaction is made up of at least two series of symptoms, and, in some cases, of three. There must be a general febrile reaction, with all the symptoms of fever, usually of a low grade and transient. Secondly, there must be a distinct local reaction at the point of tuberculous disease, as evidenced by either spontaneous pain or increased local tenderness. Thirdly, in such cases as permit of such an eventuality, there may be a marked increase of tubercle bacilli in the discharge (urine), or they may appear there for the first time. The injection is made in the arm, subcutaneously, in the early part of the day,* and the patient being in bed, the temperature is to be taken every two to four hours. If a general reaction (not too severe) is produced without a focal reaction, which is a frequent occurrence, the same dose should be repeated and it may then evoke, in addition to the general, a focal reaction. (See case of renal tuberculosis reported below.) Koch thought the fact that the general rection to the second, but identical, dose, was more marked than to the first dose was an absolutely reliable sign of tuberculosis.

I believe that very few, at the present day, would deny the specific action of tuberculin. From year to year the evidence is accumulating that points to but one conclusion. If one sees wounds in which there is firm union over a small tuberculous focus, such as is left in the vas deferens after castration for tuberculosis of the epididymis, break open directly after the use of too large a dose of tuberculin, the specific action of this agent becomes very manifest. Such an effect I have seen following a castration for tuberculosis at a time when the wound had been thoroughly healed, and again under similar conditions after a nephrectomy for tuberculosis, in which the reaction developed in the remaining tuberculous ureter.

The few selected cases reported later may also be looked upon as clear-cut demonstrations of the specificity of this reaction.

In 1907, Mohr collected the evidence in connection with tuberculin and called attention to the fact that Voges in 7,327 cases noted only 2.7 per cent. errors. Beck found in a series of 2,508 cases, in which 371 were clinically tuberculous, all were positive to the tuberculin test. Neisser reported that all tuberculous cases were positive in his experience. In Labbe's paper in 1907, he emphasizes the fact that the earlier reports of positive reaction in nontuberculous cases must be very carefully scrutinized before they are allowed to weigh against the specificity of the reaction, especially as an overdose of such a strong poison may in healthy people give a febrile reaction. He calls attention to Nocard's work on animals in which there was a careful autoptical control. In 124 cattle under these ideal conditions be obtained in 123 cases a positive reaction, all being found at autopsy to have tuberculosis. In Moeller's, 8,000 sanatorium cases the positive reaction was present in 90 per cent. (Very old

*From the Genitourinary Surgical Service of the Mount Sinai Hospital.

*R. Hollmann (*Beitr. z. Klinik d. Tuberkulose*, 1911) calls attention to the fact that reaction is more rapid during the day as noted by Riegner, Rosenbach, and others. Be that as it may, it is certain that temperatures will be taken more regularly while the patient is awake.

cases, as in the third stage, may not react.) In the experience of Lanzilotti-Buonsanti 98 per cent. of tuberculous cases gave a positive reaction. C. Franz tested 400 recruits and obtained in 61 per cent. a positive reaction, and then tested them one year later, and every one reacted then as he had done previously. Much more could be cited in favor of the specificity of the general febrile reaction. The focal reaction which is much less regularly obtained, judging from the literature that I have been able to read,* and from personal experience, is even more delicate and has very exceptionally been noted in nontuberculous lesions. In 1891, Goldschmidt, cited by Dluski, says he saw a general and a focal reaction in lepra. Pankow reported that he obtained a focal reaction in both kidneys, though only one was surely tuberculous. Whether this reaction in the second (left) kidney was due to a latent tuberculosis or not is difficult to say. The urine from this kidney was not examined, though at operation the kidney was exposed and appeared nontuberculous. (Early tuberculosis cannot regularly be recognized by looking at the kidney through an exploratory incision.) If this should prove to be a case of a normal kidney responding to tuberculin by a local reaction, it is the only case I have been able to find. Pankow, himself, must have some doubt on this score, as he says that the tuberculin test in renal tuberculosis appears to give prompt results and should be used regularly in early or obscure cases.

While Birnbaum has reported a series of cases in which the tuberculin test had been very helpful, Pankow declares that in gynecological cases examined by him he saw focal reactions in the absence of a tuberculous focus. In three cases of pelvic suppuration, of nontuberculous origin, he obtained a focal reaction. In one of these local symptoms may have been due to menses. Sahli calls attention to the fact that sensitiveness is increased in the premenstrual period. Whether this will prove to be a more common occurrence, future experience will have to demonstrate. Judging from the literature, such focal reactions in nontuberculous cases must be most exceptional.

On the other hand, it cannot be doubted that certain cases of tuberculosis, as mentioned above, may not react to tuberculin. Whether maximum doses in these would produce a reaction, one cannot say. Petruschky goes as high as 10 milligrams. Others (Mohr) up to 20 milligrams. There are some (Mohr) who think a negative response excludes tuberculosis, but to this I am not at present willing to subscribe. *A general plus a focal response is practically invariably due to a focal tuberculosis, and such a response locates the diseased area. A general minus a focal response is of no practical value, as the most careful examination cannot exclude tuberculosis in other parts which may give the general reaction.*

Before turning to the cases that follow, I wish to emphasize most strongly the fact that I am not recommending the use of tuberculin as a routine procedure in genitourinary disease. I fully appreciate the fact that this drug in a large series of cases will be followed occasionally by some unfavorable reaction such as I shall speak of later, especially if the dosage is not carefully guarded and the preparation is not scrupulously careful. All and every other means to arrive at a diagnosis must be employed, and then if the case is still obscure and the symptoms are suggestive of a tuberculous disease, and then only, do I make use of the tuberculin reaction. Others have used it to accelerate the process of diagnosis, but in such cases one must bear in mind that one is taking an additional, even though small, risk, if we are to give any credence to the few reported cases in which there was undue irritation, despite the use of what was said to be only diagnostic doses. (In this connection one can readily see how slight errors in dosage could produce untoward effects.)

Case I.—Renal Tuberculosis. P. S., 22 years of age. Since 1½ years has had increased frequency; of late every fifteen minutes; also burning on micturition. The urine has been turbid. During this time there have been three attacks of hematuria without any colic and without the passage of gravel or sand. Now has pains in both lumbar regions, especially in the left; no fever or chills. Physical examination shows absolutely nothing. There is no tenderness in the kidney regions and neither kidney is palpable.

May 24: Cystoscopy and ureter catheterization. The bladder is almost normal, except for a slight erosion behind the left ureter opening and multiple submucous hemorrhages behind and mesial to the right ureter meatus. Both ureter openings are normal and easily catheterized. The first urine obtained on the right side was blood tinged, but subsequently it became perfectly clear. The specimen from the left side was throughout clear. Both these specimens were sterile and both were injected into guinea-pigs. Examination of these specimens showed: Right kidney—Acid, slightly cloudy, urea 1.9 per cent; microscopically, few epithelial cells, few red cells, and occasional pus cells, no tubercle bacilli. Left kidney—Acid, clear, urea 1.5 per cent.; microscopically, same as the other side, except that there were a few more pus cells, no tubercle bacilli. The bladder urine was repeatedly most carefully examined for tubercle bacilli, and finally they were recovered in small numbers.

With the facts at our disposal it was impossible to locate the site of the tuberculous lesion in the urinary tract. The more marked discomfort in the left lumbar region, combined with the slightly greater amount of pus in the specimen obtained from this side, naturally pointed to this organ. The cystoscopic examination and the fact that there was pain on the right side as well suggested this side as the source of the trouble. On the other hand, the presence of tubercle bacilli in the bladder specimen, and their apparent absence from the specimens taken from the two kidneys, suggested that the lesions might be in the lower part of the tract, and not in the kidneys at all.

To clear up this rather obscure picture, to determine whether I was dealing with a supravesical, either unilateral or bilateral, condition, or with a condition lower down in the urinary tract, I administered one-half milligram of old tuberculin. There was no reaction. Two days later I gave 1 milligram, and again obtained no reaction. Two days later I gave 2 milligrams, and this time there was a systematic reaction. The temperature rose to 100.4° F. and gradually sank to normal in forty-eight hours. As there was no focal reaction, the diagnosis was not cleared up. Two days later I gave another 2-milligram injection, and this time I obtained not only a general but also a striking focal reaction. The temperature rose to 100.6° F., and there was well-marked pain in the left kidney region and distinct tenderness. There was absolutely no reaction in the region of the right kidney. In the right lobe of the prostate a tenderness developed suggestive of a second focus, which did not betray itself otherwise.

The specimen taken from the reacting kidney after this last injection now showed an entirely different picture. This urine was cloudy, contained a faint trace of albumin, and many pus cells. There was a large number of tubercle bacilli. The animal experiment corroborated the above findings, as the animal inoculated from the right kidney did not develop tuberculosis, while that inoculated with the urine from the left kidney did develop tuberculosis. It is needless to add that the operation bore out the above findings, and the kidney of the left side showed an early tuberculosis. Careful observation of the patient for some ten months after the operation has shown that the second kidney has remained normal and that the prostatic involvement is progressing favorably, apparently undergoing a process of calcification, judging from the consistency of the small involved area.

*Cf. Hohlweg for extreme view on this point, *Muench. med. Wochenschr.*, 1911, No. 51.

Case II.—Tuberculosis of the Prostate. M. J., 35 years old. As a child had a tuberculous infection of his knee; since then no further sign of any tuberculous disease. In 1912 patient developed some vague pleural irritative signs at his left base, which cleared up slowly. Thereafter he developed a series of urinary symptoms that gave him considerable distress. He had marked pain at the end of urination, with increased frequency, and the appearance of blood. There had been no lumbar pains and no colic. He had never passed sand or gravel. Examination of his bladder urine obtained by catheter showed enormous numbers of tubercle bacilli. The slide which I examined was literally covered with Koch bacillus. Physical examination showed a healthy young man without any pulmonary involvement. There was no kidney tenderness, and the kidneys were not palpable. His prostate was smaller than normal, the right half impressing me as slightly atrophic. The testes were normal. Cystoscopic examination was made under the impression that the patient was suffering from a secondary vesical tuberculosis with a primary focus in the left kidney, to which I had ascribed the earlier symptoms at the left base.

March 1: Cystoscopy and ureter catheterization: Bladder mucosa was deeply injected in trigone down to the neck. Edema well marked here, and this area bleeds readily. No ulcers and no tubercles were seen. Both ureteral meati were small, but normal in appearance, without any periureteral injection or edema. Both ureters were catheterized and almost clear urine obtained. Left kidney: Albumin 0, urea 1.3 per cent., few red and pus cells. Right kidney: Albumin 0, urea 1.5 per cent., occasional red cell and very few pus cells. Within seventeen minutes there was a strong discharge of indigocarmine. Cultures from the bladder and from each of the kidneys were sterile. So far it seemed that my original suspicion was correct. Careful search in slides from the kidney urines, carried out by three examiners, one of whom spent eight hours in the search, failed to show any tubercle bacilli. This might occur despite the presence of a renal tuberculosis, though it was surprising in view of the myriads that had just been found in the bladder specimen.

To assist in the elucidation of this obscure state of affairs, guinea-pigs were inoculated with sediment from each kidney. The reports on these would have obscured the case much more if a positive diagnosis of prostatic tuberculosis had not been reached by the use of tuberculin before the guinea-pigs had rendered their verdict, as both pigs developed tuberculosis. Whether this positive guinea-pig reaction was to be ascribed to a very slight contamination of the ureter catheters in their transit through the bladder, or to an excretory phenomenon through normal kidneys, it is difficult to decide, though the former explanation I consider the more likely. The subsequent history of the case excluded the possibility of a bilateral renal tuberculosis. If the former explanation be correct, this case illustrates the possible danger of carrying infectious material from the lower to the upper tract. It would seem from this case that the animal experiment is much more delicate than the slide examination, which my experience does not bear out. The two methods must always be used together, as I have repeatedly found tubercle bacilli in the slide when the animal experiment was negative.

Returning now to the case under discussion, it is evident that I had not reached any definite diagnosis, despite the fact that I had availed myself of the most approved methods of diagnosis, and carried them out with the greatest care. After the cystoscopy the patient was kept in bed and the vesical symptoms gradually disappeared. Still the bladder specimens contained tubercle bacilli, and my attention was naturally directed to the lower tract. I catheterized the bladder before and after gentle massage of the prostate, and found what we took to be an increase of bacilli in the second specimen. This I regarded as presumptive evidence of local disease, and to test this conclusion, which was so opposed to my original interpretation, I decided to use the tuberculin test.

Under 1 milligram of tuberculin all the vesical symptoms returned—hematuria, pain, and increased frequency. At the same time there was a mild febrile reaction and locally the half of the prostate that I had regarded as atrophic became markedly tender for the first time. This reaction rapidly subsided, and the patient was placed on therapeutic doses of tuberculin, with the result that all the symptoms of vesical irritation have disappeared, and no tubercle bacilli or red cells were to be found in his urine during the past six months.

Remarks.—I believe this is as obscure a case as one is likely to see, and without the careful use of tuberculin the definite diagnosis of the localization of the disease would not have been made. Everything pointed to a supravesical origin of the trouble, except the smaller size of the left half of the prostate. That this smaller part of the prostate should be the source of trouble, I naturally did not suspect. It was only after finding a marked disproportion between the contents of the kidney specimens and the bladder specimens that I was forced to consider seriously the slight disproportion in the size of the two halves of the prostate. My surprise was all the greater when I obtained a local tuberculin reaction in the slightly smaller half of this organ, rather than in the other half, which, if anything, impressed me as the more pathological.

Case III.—Tuberculosis of the Epididymis. M., 25 years of age, complains since several months of a small nodule in the left side of his scrotum. This has not grown materially, nor does it occasion any serious pain. On examination only the local condition was detected. The right testis was normal, but in the left half of the scrotum there was a small mass, running from the summit of the organ forward and downward, to about the center of its anterior surface. This mass was distinctly nodular and felt very much like a tubercular epididymis in every particular, except that its position was most unusual. In shape and consistency, in absence of any great tenderness, in slow growth, etc., it suggested a tuberculosis of the epididymis. Examination of the course of the vas suggested that the testicle had been rotated on an axis drawn through its center horizontally from side to side. The vas usually descends well down to the lower pole of the testis, and then bends up over the posterior aspect of the organ to run on to the epididymis. In the case under discussion, the vas extended only as far as the center of the posterior surface of the testis, and then turned up, to disappear in the epididymis. This made it very probable that the organ had been rotated in the way mentioned above. This unusual state of affairs did not convince all who saw the case, and some still favored the diagnosis of a new growth. To clear up the nature of the process, I gave the patient ½ milligram of tuberculin, and obtained a general and a very distinct local reaction, as evidenced by well-marked pain in the area under discussion, and distinct increase in local tenderness. This confirmed the diagnosis of tuberculosis of the epididymis in an abnormally turned testis, and subsequent operation bore out this conclusion.[4]

[4]In this connection it is of interest to call attention to the fact that in Kocher's monograph on testicular disease, etc., he remarks that he has seen only two such rotated testes and that both showed tuberculosis of the epididymis.

If now we turn to the literature of this subject, having cited these typical cases illustrating the more usual locations of tuberculosis in the genito-urinary tract, we see that others have been able to obtain valuable information in their cases by means of this same reaction. All the cases in this field that I have been able to find were renal or vesical tuberculosis. According to Wagner's statement, Czerny was the first to use this agent as above described, and I shall quote this case because of the historic interest inherent in it.

"A girl of 18 years had a pyonephrosis of unknown origin and to determine the nature of the process a tuberculin injection was made. There was a general and a focal reaction and the urine became clear, pointing to the conclusion that the other kidney was not diseased and that the pus was derived from the enlarged kidney alone. Next morning the urine was full of pus again, and now for the first time tubercle bacilli were found in the urine. As the patient was in no wise hurt by the tuberculin, the test was repeated several times and always with the same results. At operation the correctness of the diagnosis thus made was verified."

Koranyi, Birnbaum, Karo, Pankow, Hock, and Brueckner have had similar results in cases of renal tuberculosis. Israel also uses the so-called provoca-

tive injection when the case is obscure. In Brueckner's case the test was particularly valuable as in the child in question cystoscopy was impossible. In Karo's case the test showed a bilateral process when a unilateral one was suspected. In this case a careful ureteral catheterization with a complete examination such as I employed in the above cases might have demonstrated the facts that were shown by the tuberculin test.

From this brief review of the literature it is evident that very few surgeons have availed themselves of the possibilities of the tuberculin test. In my search of the literature for cases such as I have reported above, I found no reference to the use of tuberculin as a diagnostic aid, except in renal (secondary vesical) tuberculosis, and in these cases it appears to have been used very exceptionally. Whether this is due to the general discredit into which tuberculin originally fell, or not, it is difficult to determine.

Apparently, most surgeons prefer to expose the organ when in doubt, which surely is a more dangerous procedure as well as a more unsatisfactory method of diagnosis than that under discussion. The exploratory operation will have its field of usefulness, but it should always be the method of last resort. If the tuberculin reaction is focal, as I have repeatedly seen in renal tuberculosis, one starts the operation with a well-considered plan, knowing just what one has to do. Exploratory inspection of a kidney in the early stages of tuberculosis is a most unsatisfactory method of diagnosis, and frequently leads to mistakes, and just in this type of case one may be fortunate enough to clear up the diagnosis with tuberculin by obtaining a focal reaction. If this fails the exploratory operation will be in order.

From what I have said, as well as from what I have hinted at, it must be evident that I do not use the tuberculin test without first carefully studying the case under consideration. I make it a rule to employ every available means of diagnosis before resorting to the use of tuberculin. When the diagnosis can be made without tuberculin, which is the rule rather than the exception, I make no use of this preparation. Moreover, in patients with advanced tuberculosis in the lungs or other parts, I would not use this poison. Koehler advises against its use in convalescents, and Mohr against its use in heart disease. To avoid giving the patient too large a dose as the initial injection, the advice of Diem, borne out by the experience of T. B. Sachs, is worth following. Diem advises testing the susceptibility of the patient by doing a v. Pirquet test first,* and then gauge the size of the tuberculin dose by the severity of the skin reaction, using even less than one-half milligram as the initial dose if there is a marked skin reaction. Sachs has noted that when the skin reaction is rapid and marked in degree such cases usually respond to minimal doses given subcutaneously. In addition to the above precautions, one must be very careful that one has not only obtained the proper preparation but has also given the proper dose.

As far as the dangers of the use of tuberculin are concerned, it must be evident that I think that there are some dangers inherent in this preparation. This belief has been forced upon me not by any personal experience but from a perusal of the literature. In the literature one finds many authors declaring that there is no danger in the proper use of tuberculin, while others just as vehemently declare it is dangerous. Mohr says it is not harmful; Labbe says ill effects are practically unheard of to-day. Servaes says that Moeller made 20,000 injections without any bad effects, and that Bandelier, Freymuth, Kremser, and he himself have had the same experience. He concludes that injuries are a fraction of 1/1000 part and that we are no longer justified in speaking of the dangerousness of a probatory injection.

In a personal communication from Dr. L. Rosenberg of the tuberculosis station of the Montefiore Home at Bedford, he says: "Relative to any possible unpleasant effects from the diagnostic use of tuberculin, I desire to say that we have never observed anything to cause us any anxiety, even in former days when the maximum dose was 10 milligrams. In other words we consider the subcutaneous use of tuberculin for either diagnostic or therapeutic purposes absolutely safe when properly given. By properly given, we mean when there are no constitutional disturbances such as high fever, etc., and no nephritis or other complications that contraindicate the use of the drug. We only employ the test when the history and the physical signs are ambiguous."

All the more recent evidence goes to show that this drug is not dangerous when used carefully and under the restrictions mentioned above. Still in the earlier and occasionally in the more recent literature we find warnings against the use of this drug. Heubner, for instance, thinks he saw two cases of miliary tuberculosis develop after its use, and Foss has reported a hemoptysis. It is of course difficult to say that these cases did not have their miliary tuberculosis at the time of injection. Still such accidents are theoretically possible, as we know how powerful the drug is as an irritator of tuberculous lesions, and to avoid such accidents great care should be taken, as was suggested above, in recommending Diem's procedure of a preliminary von Pirquet test.

In conclusion, I wish to emphasize the fact that the use of old tuberculin as a diagnostic aid should not be ignored, that it has a definite field of usefulness as an adjunct to other methods and it should regularly be employed only after other methods have rendered an unclear verdict, that is, in obscure cases, and then with the carefulness and precautions mentioned in this paper.

*Very rarely this may mislead, as some patients with a negative v. Pirquet reaction may respond to minimal doses of tuberculin, even as low as 1/100,000 milligram, administered subcutaneously.

THE PAROXYSTIC ATTACK OF METATARSAL PAIN.

(MORTON'S METATARSALGIA.)

By CECIL KENT AUSTIN, M.D.,

PARIS, FRANCE.

An astute and very observant woman once said to me: "The trouble with you doctor-men is that you do not pay sufficient attention to the minor ailments; nothing interests you but serious cases. If I were a physician I should specialize in trifles, and I'll wager I should make a fortune!" I was young at the time and scouted the idea as pernicious heresy; but experience has since taught me that the lady was altogether right. What this critic did not know, however, was that the reason why practitioners, and particularly young men, are so weak in the human complaints of lesser importance is that, practically speaking, such cases never occur in their hospital experience; in fact, many of them are not even referred to in the textbooks; that is the sort of knowledge that a physician only acquires by dint of years of battling with his trying though educational adversary the private, paying patient. Shall I ever forget the ignominy of my first encounter with a plantar papilloma, a wretched invention that I had previously never heard of? Of what use were years of experience with cancers and major surgical cases in dealing with that little piece of practical work? After several months of scraping, burning and bunion plasters, the patient went home to Scotland on a vacation; and there a more enlightened brother cut the thing out in a jiffy, afterward sending the youth back here to cover my head with derision.

However, even long years of practice are not sufficient to protect the physician altogether from the risk of such downfalls to his pride; and it is because quite recently I had a narrow escape from again coming to grief over a very simple matter that I am relating this tale. Although now in my third decade of practice my attention had never previously been directed to what is known as Morton's painful affection of the fourth metatarso-phalangeal articulation. Now Morton was a Philadelphia; consequently this complaint may be better known at home than over here. But in this community at least I have the best of reasons for believing that I am not the only man to whom this disorder was unfamiliar even by name; therefore, in case there are still others in a similar plight, a brief account of my latest experience may prove a useful lesson.

The patient, a woman of sixty, short, and rather inclined to be heavy, began to suffer with her *left* foot several years ago—the exact date is uncertain. There had been no accident in her history, nor had she ever had any of the ordinary signs of a depressed arch; she did, however, sprain her *right* ankle a couple of years ago, which may possibly have thrown extra work on the left limb. Her description of these seizures, which come in severe attacks separated by periods during which she is quite comfortable, is as follows: She will be walking along feeling perfectly well when suddenly she will be taken with a violent pain in the ball of her foot, always starting precisely at the fourth metatarso-phalangeal joint; this soon spreads to the entire sole, and, if she continues to walk, will extend onward up to the knee, and finally produce a sensation of nausea at the epigastrium. The suffering is intense enough to bring tears—"like a red-hot poker being twisted around in the flesh;" on some occasions even she is quite unable to proceed any farther, but will sit down wherever she may be and take her shoe off, preferring to walk home in her stocking, if no cab is available, to enduring the agony any longer. During an attack the pain is constant, and a recent crisis lasted three entire days. A paroxysm may come on after fatigue, or be induced by treading on a small pebble; again it may break out on the smoothest kind of a floor, such as in her bedroom. One of her worst seizures started on the polished wooden parquet of a picture gallery. The attacks have always been quite similar to each other, varying only in degree; but of late they are becoming more frequent. She now never feels sure of her foot, and is apprehensive about going off on a walk in any but frequented places, lest at any moment the pain should come on and she be unable to reach home again. More or less unconscious sparing of the left limb is gradually making her lame.

Examination shows that she wears a fairly sensible shoe. She claims that she is always better in snug than in roomy footgear. The toes are bent, but without corns. No callous patches on the ball of the foot; neither redness, nor swelling, and very little sensitiveness to pressure. Pulling, twisting or manipulation of the fourth toe cause no discomfort. Movements of toes and feet are similar on both sides. The *x*-ray picture reveals no lesion beyond a foot thrown out of shape by civilized footwear.

Such was the problem before me. I felt that the case was of a mechanical nature, and that neither gout, rheumatism, nor neuralgia would answer in this instance, and I was ruminating on the disorders of the transverse arch when I unexpectedly came on the brief mention "metatarsalgia" in Osler's textbook—not more than half a dozen lines. This afforded me no little gratification, as I imagined that I had hit on something quite unusual, from which much *kudos* might ensue, and I at once wrote to Sir William asking him if he would let me know who Morton was and where he had published his original memoir. My candor of soul must have appealed strongly to the professor's sense of humor; but he was good enough to send me the information desired, adding, however, the dry remark that as regards the rarity of the condition he had seen "a great many cases." This is all very well; he had been a colleague of Morton at the Philadelphia Infirmary, had seen him operate for the relief of the complaint, and had in this way had his attention strongly drawn to it. But one of two things is quite certain: either this disorder is far less common in Europe than at home; or it is in reality one of the rarer occurrences in medical practice.

Thus a surgeon of unusually wide experience, to whom I spoke about the matter, had never been called on to treat a case, and knew it only vaguely from his reading. And what makes me suspect that it cannot be so very common even in America is, that although Morton's original description appeared in 1876, fifteen years later, in 1891, Dr. Bradford of Boston makes the following remark in a paper published in the *Boston Medical and Surgical Journal:* "It is somewhat singular that an affection that is not infrequent, in these days of thorough investigation of all ailments, should have attracted but little attention, either in the researches

of surgeons or of neurologists." Now it may have seemed "not infrequent" to Dr. Bradford, since owing to his special branch of practice such cases naturally turn to him for relief; but this metatarsal variety of pain is a serious matter, very serious in some cases, and if it were really of very common occurrence a great deal more would most certainly have been heard on the question than has been the case so far.

Once the practitioner's attention is called to the existence of this condition its diagnosis is really a very easy matter; there seems, in fact, nothing with which it can be confused. It is observed generally with women; thus out of the fifteen cases on which Morton's original paper was based as many as thirteen were women. It usually occurs in middle life, one writer even stating that it has never

Roentgen picture of the foot in the case of metatarsalgia, showing no lesions.

been met with before adolescence. Some cases follow traumatisms of various sorts, and treading on a stone is often mentioned among them; others gradually develop from pressure; while still others show no perceptible etiology. Its frequency in middle life would seem to point to some giving out of the transverse arch of the foot, and it would be interesting to note whether in a series of cases the patient's weight was appreciably more than the normal; in my particular instance, age, weight, and traumatism were all present. From the different accounts the pain is very severe. My patient came to my house one day in tears; in others morphine has been used; it has been reported to produce convulsions; and in one instance amputation of the limb had been seriously discussed, the patient's life being unendurable.

But the general tableau of the occurrence is really altogether characteristic, the diagnosis being one of those that ought to be made at a distance; a woman of mature years, who is subject to sudden seizures on the street of agonizing attacks of pain in the outside of the ball of the foot, pain rising to the knee and finally causing nausea, pain leading her to sit down anywhere regardless of appearances and remove her shoe and manipulate her foot, the foot on inspection being quite free from redness, swelling and even sensitiveness, can only be suffering from paroxystic metatarsalgia, nothing else will do.

It seems practically certain that the condition is due to a nipping of one of the branches of the external plantar nerve in the fourth intermetatarsal space, due to spreading of the transverse arch, which allows the second and third metatarsals to sink down. The pillars of this arch are formed on the inside by the head of the first metatarsal, and on the outside by the fourth and fifth heads acting together; the second and third constitute the vault. Now the heads of the first three metatarsals are normally about on a line, and are so fastened together as not to admit of much movement; but the fourth falls back of this transverse line, and the fifth considerably more so, they being both much more loosely connected than the other three. What seems to occur, then, is that the transverse arch spreads through some such cause as age, weight, or weakness, and the inner portion of the arch sinks down, throwing the shaft of the fourth metatarsal against the head of the fifth and base of its phalanx—in a word, against the metatarsophalangeal joint—catching the nerve between them. (See the *x*-ray picture.)

Treatment is either palliative or radical. In the first instance an attempt is made, by the use of tight bandaging or the wearing of felt pads or leather inner soles so fashioned as to bring pressure upward behind the heads of the second and third metatarsals, to prevent the foot from widening when weight is thrown on it, and the arch from lowering. Radical treatment consists in excision of the fourth metatarsophalangeal joint with its adjacent soft parts, an operation that has now been many times performed, with, it is claimed, conspicuous success. In my personal case the condition has apparently been quite relieved by a well-fitting shoe and a bandage passing several times around the transverse arch so as to prevent the foot from spreading.

THE RATIONAL TREATMENT OF ACNE PUSTULOSA WITH SPECIAL REFERENCE TO THE BACTERINS.*

By PENN G. SKILLERN, Jr., M.D.,

PHILADELPHIA.

INSTRUCTOR IN ANATOMY AND IN SURGERY AND ASSOCIATE IN THE WILLIAM PEPPER CLINICAL LABORATORY, UNIVERSITY OF PENNSYLVANIA; PHYSICIAN TO DISPENSARY FOR WOMEN, GERMAN HOSPITAL; FELLOW OF THE PHILADELPHIA ACADEMY OF SURGERY.

The successful treatment of acne pustulosa must be based upon a clear conception of the bacteriology, histopathology, and relation of the disease to development and to constitutional disorders.

Primarily, let us consider the factors in the genesis of acne. According to Whitfield,† these are: (1) seborrhea; (2) comedo formation; (3) suppuration around the comedo. Seborrhea oleosa is hypersecretion of the sebaceous glands which induces pathological sequelæ. Because of close anatomical association it is often accompanied by hyperidrosis. Etiologically the internal secretions of the sexual glands play a rôle, because seborrhea is commonly met with in adolescent males, during the development of the beard, at which time the sebaceous glands assume great activity but not immediate regularity of action. Seborrhea is also excessive in females during development of the mammary glands, which, it will be noted, are themselves modified sebaceous glands having to do with the production of fat. It is also produced by overindulgence in sugars, starches, and fats, by malfunctioning of the digestive tube, and by exposure to a hot, moist atmosphere, or the wearing of excessive amounts of woolen clothing.

Comedo or blackhead formation is a purely mechanical process involving the orifice of the sebaceous follicle. The gland responds by hypersecretion and a modified sebaceous cyst is formed. The "plug" itself consists of whorls of epithelial cells whose layers contain clusters of the microbacillus of Unna and Menahem Hodara (Sabouraud). Dissolved in cedar-wood oil this fatty seborrhic plug reveals large numbers of the demodex folliculorum of Simon and Gruby, the rôle of which doubtless is to carry the microbacillus (Sabouraud, *Brit. Med. Journal*, Aug. 10, 1912, p. 287). The latter has been proven by Halle and others to be a strictly anerobic organism which may be cultivated by emulsifying the comedo and planting it upon gelatin covered with a thin layer of sterilized butter (Mauté). A simpler and equally valuable medium is that employed by Hall, and strongly recommended by Dr. Richard L. Sutton (personal communication) of the University of Kansas. This culture material, which is a glycerin (1 per cent.) gulcose (2 per cent.) agar, neutral to phenolphthalein, is easily prepared, and, by the aid of Buchner's apparatus, pure cultures of the *Bacillus acnes* may be secured without great difficulty.

Whitfield concludes that the first step in comedo formation is the growth of the microbacillus in the mouth of the sebaceous follicle, and that the follicle, stimulated by the toxins liberated by the organism, treats it as the epidermis always treats a non-pyogenic foreign body, that is, by attempting to encyst it with successive layers of cells. The result is acne sebacea.

The way is now prepared for secondary invaders, and of these the most common is the *Staphylococcus albus* of Welch. Entering the mouth of the follicle this organism lodges between it and the comedo, and by its activity surrounds the comedo with a lake of pus. The acne sebacea now becomes an acne pustulosa, and if the depths of the sebaceous follicle are invaded, surrounding infiltration occurs with the production of acne indurata. The bacillus may be absent in smears but present in microscopic sections of the acne lesion. From a study of such sections Whitfield found that abundant colonies of the *Bacillus acnes* without colonies of staphylococci result in comedo without inflammation; whilst abundant colonies of the microbacillus plus colonies of the staphylococcus result in comedo plus suppuration. This would appear to establish the non-pyogenic character of the *Bacillus acnes*.

In the treatment of pustular acne I believe that the common cause of failure is the employment of and reliance upon but one remedy. Success depends upon attacking the malady in several ways at the same time. In the first instance, dyspepsia, constipation, or anemia, if present, should be corrected. Start at the very portals of the digestive tract, and see that the patient has a good and complete set of teeth, and that the gums are in a healthy condition. Then instruct the patient to eat at regular intervals and to masticate his food thoroughly, even to fletcherize. Stop excess of starches, sugar, and particularly fat (see Montgomery and Culver, *Jour. Cutan. Dis.*, 1912, p. 319). Alcohol in any form is bad. This regimen excludes the use of fried food, candy, and pastry. Constipation should be corrected by establishing the habit of regular evacuation after breakfast each morning. Anemia, if present, is best combated by appropriate exercise in the open air, and the ingestion of raw egg three times daily, after or between meals. These methods, if persisted in, are better than the swilling of gallons of empirical drugs. The usual directions of "regulate the diet, open the bowels, and exhibit such-and-such a drug" are not specific enough. For instance, a patient with acne is not an invalid. What he most needs, in nine cases out of ten, is correction of faulty habits. He is physically capable of availing himself of many simple measures that a sick person confined to bed cannot begin to do. Acne is seldom seen in sailors or in others who lead an active outdoor life.

The local treatment may be summed up as follows: If possible, a few exposures to the *x*-ray to cause temporary suspension of sebaceous activity. Then express every visible comedo, thus nipping in the bud many future acne pustules. Facial massage may be of value. Puncture each pustule, and, after bathing in cold water, apply a small Bier cup. Afterward swab the lesion with a mixture of pure phenol, 3 parts; camphor, 2 parts (Abraham). Have the patient use a good boric acid soap (or, better, hand sapolio or Ranier soap) with tepid water on his face at least twice each day, and at night apply lotio alba (zinc sulphate, precipitated sulphur, and sulphureted potash, of each 2.0 to 4.0, rose water q. s. ad 100.0), rubbing in well. If too much irritation results, substitute a soothing application, as rose water ointment, for a time. Finally, when, in conjunction with the above measures, a properly prepared autogenous vaccine is employed, in strong rather than weak doses, a permanent and fairly prompt cure may usually be promised. In those instances where the staphylococcus predominates, it

*Read before the John Morgan Society, University of Pennsylvania, April 10, 1913.

†*Brit. Med. Journ.*, Aug. 10, 1912, p. 287.

is well to start out with an autogenous staphylococcus vaccine, switching over to the *Bacillus acnes* suspensions later. While the carrying out of a successful plan of treatment is often taxing on the patience of both physician and patron, the results more than justify the labor expended.

Old acne scars and indurations, if superficial, may be improved by triweekly vibratory massage with the electric rubber cup. If deep nothing short of excision of the most conspicuous ones will suffice. After intradermal injection of a few minims of a 2 per cent. solution of novocain with 1-3000 adrenalin, an elliptical incision is made with a sharp scalpel around the scar down to the subcutaneous fat. Careful approximation with an intradermal silkwormgut suture results in an inconspicuous linear scar.

241 South Thirteenth Street.

SOCIAL SERVICE IN HOSPITALS AND DISPENSARIES.

By ISABEL M. STEWART, R.N.,

NEW YORK.

DEPARTMENT OF NURSING AND HEALTH, TEACHERS COLLEGE, COLUMBIA UNIVERSITY.

All hospital service is social service, in that the hospital as an institution exists for what it contributes to the welfare and happiness of human beings. The great problems of the hospital are all at bottom social, for disease produces not only individual suffering and inefficiency, but its results penetrate deeply into the very structure and life of both the family and the community, and into every phase of that life. Not only the results, but the causes of disease are rooted in social conditions. Just how closely the social and the physical factors intertwine in the everyday hospital problems may be illustrated by one or two typical cases. Here is the very common case of the scrawny baby suffering from malnutrition, or anemia, or rickets. What brings it to the hospital? A little investigation reveals a one-roomed home in an insanitary tenement, the mother working to support a family, too poor and also too ignorant to supply them with the necessaries of life. Back of the poor food and the bad housing, however, lies the problem of a deserting husband, and back again of that, perhaps, incompetence, non-employment, and the ever-present problem of persistent, depressing poverty. Here is a hollow-chested young man with the typical flush and cavernous cough which even an amateur could diagnose. What brought him here? Tuberculosis, of course; but back of this is a sweat-shop or a stuffy, crowded store, or the fatigue of a twelve-hour day which broke down the man's resistance and made him an easy victim of the ever active and vigilant *Bacillus tuberculosis*. Numberless other cases will suggest themselves; diseases caused or complicated by intemperance, by prostitution, by industrial occupations and conditions, by social habits or customs, many of them not at all confined to the poorer classes.

Such problems are not new. They have engaged the attention of serious people both inside and outside of the hospitals for many hundreds of years. With the deaconesses and sisters of charity and the brothers of the religious orders who helped to found the early hospitals, the physical welfare of the patient was usually secondary to the spiritual and moral welfare, and the ultimate aim was, of course, not to root out physical disease, but to get the soul ready for a happier and holier life. Poverty and misery were considered as not at all bad in themselves, but rather as a salutary means of spiritual discipline through which the soul might reach its highest development. Still, though they did not view the matter in our modern light, their spirit was essentially one of social service, and they did do much to fortify and support and comfort their unfortunate patients in material as well as spiritual ways. Still more practical forms of hospital social service are recorded in some of the reports of the more modern hospitals. Patients were provided with food or clothing or appliances of one kind or another, they were visited and read to, employment was secured for convalescents, and many kindly and charitable services were rendered. This kind of home missionary work was fairly well systematized under the Samaritan Funds of English hospitals which date back as far as 1723, and which were usually organized and administered by boards of women under the advice of hospital officials. Such attempts at hospital social service were more or less individual and spasmodic. It is essentially the "Lady Bountiful" type of charity—palliative, not preventive or constructive.

We see a rather better organized form of hospital social service in the work of the almoner of the English hospital. In older times the almoner was employed by the hospital for the purpose of preventing people from imposing on hospital charity and of administering relief funds to needy patients. As the social and medical sciences have advanced the work has become more educational and preventive in nature. The almoner has tried to establish habits of foresight and thrift in poor families, to improve conditions of living, and to carry the work of the hospital into the homes.

The organized movement in America is quite recent. In 1901 Dr. Emerson of the Johns Hopkins Medical School organized a branch of the Charity Organization Society among the medical students of the university. This work was not medical in character. The aim was to give the students some really concrete idea of how the poor man lives and works and thinks, and what his problems are. It was more for the enlightenment of the student than actual service to the man. Incidentally, it threw a good deal of light on the causes of disease and the futility of many existing methods of medical treatment. In 1905 Dr. Cabot's historic experiment was tried in the Massachusetts General Hospital of Boston. Dr. Cabot was not satisfied with the very superficial work that he felt was being done in many branches of the hospital and dispensary. There seemed to be conditions which he could not remedy and causes which he could not reach by ordinary hospital methods, and the human side of the work was, he felt, often sorely neglected. Miss Pelton, a visiting nurse, was employed to follow up special cases from the dispensary, to find out what home conditions were responsible for their troubles, and to advise and instruct and help the patients in every way she could. The information gained was so illuminating and the results so striking that a separate department or bureau of social service was organized in connection with the dispensary, to which all such cases could be referred. Bellevue Hospital came next, in 1906, and since that time every year has seen the organization of numerous departments all over the country. There are

now thirty social service bureaus in New York City alone. Most of these are an integral part of the hospital, while some are maintained by individuals or organizations outside.

The reasons for this significant modern development are probably to be found in the temper and ideals of our own time. Hospitals, as well as schools and churches and political organizations, are becoming self-critical. They are asking themselves whether they really are fulfilling their whole duty in the light of our modern conceptions of social responsibility. They are beginning to analyze and test their results to see whether they measure up to our modern standards of efficiency. What is the use of spending two dollars a day for six weeks to put this patient on his feet if the whole job is undone for lack of a little care in convalescence? What is the use of nursing a youngster back to ruddy health only to have him return as bad as ever in a few weeks? Some cases have been readmitted again and again simply because they could not live in their home environment. The question used to be, "How many patients did we treat—how many dollars did we spend?" Now they are asking, "What permanent, tangible results have we to show for the money expended?"

Physicians are also beginning to criticize their own results from the economic and social point of view. "What is the use," they say, "of trying to patch up a headache when the source of the trouble lies in worry or in overwork? Why keep on prescribing iron for the anemic child who lives in a horrid cellar and never sees good food? Why spend hours in examining and testing and advising if the patient is too poor or too ignorant to profit by our advice?" Another baffling feature of the present situation is that the agencies of treatment are less within the physician's own grasp than they used to be. It was easy to write prescriptions for all comers, and even to supply the drugs, but it is not so easy to supply the treatment which has to a large extent superseded drugs. Hygienic surroundings and good food and careful nursing, and those intangible influences that lay hold on the mental and spiritual forces which lie in the individual himself—these are not to be doled out at a dispensary window by any ordinary paid hand.

The social service department has helped in solving a good many of these questions. The medical man approves of it because it helps to complete his work—it makes it effective. The hospital approves because it saves the needless waste of hospital resources; it prevents so many readmissions; it helps to prevent the abuse of the hospital resources, and makes the hospital a more popular institution with the public. The nurses approve heartily because it assures to the patient that kind of human help which they themselves have always tried to give in some degree, but can give so inadequately in the rush and hurry of the busy ward. Medical social service from this point of view is simply a logical and necessary adjunct to the medical service—just as good nursing was found long ago to be an absolutely essential element in getting patients well—just as school nursing at the present day with its follow-up work and home teaching is found essential to effective medical inspection. It would seem then that medical social service is largely an extension of the nurses' duties on the wards, with more time to concentrate on the social and educational side of nursing work, which Florence Nightingale defined as "helping people to live."

There is, however, another and different conception of social service which is held by many trained social workers. Disease, they say, is only one element in a much larger situation. It is a symptom of some morbid social condition which affects not only the individual but the family unit, and it is the integrity of this unit rather than the welfare of the individual that must be the primary consideration. Physical welfare is important mainly as it contributes to the preservation and development of character. The patient is not a medical case but a man, and probably the father of a family, and the question is not so much whether we are helping him to get well, as whether we are helping him to be of some use to society and to himself when we are through with him. The hospital is only one in a chain of cooperative agencies which have for their aim the building up of a strong, healthy, and morally sound social fabric.

From this standpoint the social service bureau is a sort of sister to a Charity Organization Society. Its function would be to investigate, to diagnose social maladjustments and maladies, to collect and to organize social data, to keep the hospital in touch with social needs and conditions that bear particularly on its work, and to administer such treatment, help or advice as will aid in ultimately strengthening the moral fiber and conserving the personal and family life of the patient.

It would not seem to be impossible to bring these aims together in hospital social service work and to do justice to both. It has been done very successfully, though it must be admitted that it requires unusually sound judgment to choose wisely between the claims of the sick man and the possible pauperization of his family, or between the immediate relief of the disease and the ultimate good of the patient's character. Personally, I feel that the hospital should concentrate on its business of getting people well, utilizing all the agencies it can for that purpose and reaching out into the community as an educational force, particularly along the lines of preventive medicine.

In regard to methods of work, the social service bureau does not attempt to go outside of the hospital for its patients, indeed, as the work is at present, only those presenting the most acute and distressing problems can be attended to. These are referred to the bureau by nurses and physicians, or are found by the social service worker in her visits to the wards or outpatients' department. The clinics present endless material, especially the children's clinics. In a large bureau one worker is detailed for the children, another for the maternity patients, another for nervous and insane patients, and so on. A good deal of visiting must be done in the homes to keep in touch with conditions there. Here voluntary workers may sometimes be of service, and the experience and training afforded is often of the greatest benefit to the visitor herself. It is Dr. Cabot, I think, who recommends this work as the best known treatment for certain forms of neurasthenia, or "nervous prosperity," as the popular malady has been called.

The work among the patients is so varied that one can do no more than indicate a few general lines of activity. There will be patients who need to be sent to institutions, such as schools and homes for the deaf, the epileptic, the feeble-minded, or sanatoria for consumptives, or convalescent homes. Others will need to have help in securing suitable

employment. The most essential thing in other cases will be just diversion, occupation, friendship, or good advice. In very needy cases, food, medicine, clothing, etc., are sometimes given, though cases that need relief are usually turned over to agencies which exist for that purpose. The educational work is one of the most important of all. Sometimes this teaching is done in classes, but usually it is individual. The teaching is very concrete and practical—everything from cooking and modifying milk to mental suggestion and sex hygiene. The work of investigation and recording is essential as a means of testing up results. Statistics, though notoriously dry reading, have been made the basis for much-needed social reforms and also for adjustments in the hospitals' own methods.

I will not undertake here to describe all the qualifications of a social service worker. Although a few men have specialized in this work by far the largest number of workers are women. Whether she be a nurse or a physician or a trained social worker it is of the highest importance that the worker should be the right kind of a woman, and that she should have an adequate preparation —first, a liberal education, then a training both in the medical and social aspects of her work. It would seem that other things being equal, the nurse has already at hand by far the larger proportion of the necessary equipment. Patients know her and have confidence in her. The doctors are accustomed to working with her and are able to discuss professional matters freely, without embarrassment or unnecessary explanation. A large part of hospital social service work will have to do with sanitation and hygiene, with the explaining or carrying out of medical orders, with the handling and care of sick people, and particularly with the observation of symptoms and conditions, in most of which the nurse is already well prepared. In addition to this, however, she must have the larger social point of view, must be acquainted with the aims and ideals of modern constructive philanthropy, and with all the social agencies which cooperate with the hospital in social service work.

But such preparation, such a point of view, is not needed in hospital social service alone. Practically the same problems are to be met in district nursing, tuberculosis and infant welfare work, in school nursing, and in all the newer branches of public health work which are opening up with such rapidity all over the country. I maintain that the same social point of view is needed in all hospital and even in private nursing work. If the hospital is a social institution, founded and maintained to carry out a definite social function, every worker in that institution is engaged in public welfare work. It is particularly important that the nurses, who are closest to the patient and who are to a great extent responsible for the spirit and atmosphere of the institution, should see themselves in the light of this larger social function. For nursing *is* social service. It is a great mistake to assume that the nurse is concerned wholly with the scientific or administrative or medical aspects of hospital work. Her interest in nursing is usually essentially human and personal. The spirit which calls her into the hospital and carries her through her very difficult training is primarily the desire to be of service—to help people. It was this spirit which built up the splendid traditions of nursing service, extending backwards for hundreds of years. The shameful prostitution of nursing, and the unspeakable horrors of the later hospitals even up to 50 years ago, were remedied only when Florence Nightingale brought back into the service of the hospital and of humanity the enlightened social spirit of educated and earnest women. For a time they were practically the only body of trained social workers. The great reforms that followed in the care of the sick poor in hospitals and workhouses, in the slums of great cities, and in isolated rural districts, are sufficient proof of the intense enthusiasm for humanity, the unselfish devotion, and the practical efficiency of those nursing pioneers.

That spirit is not dead. Splendid women are still setting aside far easier and more lucrative employments to enter nursing schools, so that they may be prepared for this real, vital form of human service, and a large proportion of graduates each year find their way into the various branches of social or public health nursing, such as district nursing, school nursing, tuberculosis and baby welfare work.

As hospitals have multiplied; as the nurses' duties have become more exacting and increased emphasis is laid on the scientific and technical aspects of their work; as the hospital itself has become more highly organized, the human element tends sometimes to be neglected in the relentless demands of the system and the machine. If the officials and staff of some of our hospitals are (as is alleged) often lacking in consideration for patients, blind to human needs, and unable to grasp the larger significance of the service in which they are engaged, the reason is not to be found in the nature of the work itself, but either in the type of men and women who are selected for it, or in the fact that the workers are simply overwhelmed by the multiplicity of manual and routine procedure, so that they have no time to think of the more personal and human needs of their patients. Another undoubted reason is that their attention has not been directed to those large social backgrounds that lie behind the very common phenomena of disease. One needs both to know and to feel these things deeply in order to put one's self into the right relations with sick people.

Perhaps the time will come when we will consider a course of lectures on the sociology of disease and a short term in the social service department as essential in the training of a nurse as the course in anatomy or the term in the operating room; and the most economical of hospital boards may eventually come to feel that in the end it pays better to give its nurses time to care for their patients' social and mental as well as their bodily welfare instead of utilizing all their time and energy in the endless routine of household procedures which belong far less strictly to the duties of a nurse. Internes need this social training quite as much as nurses, and one might hope that it eventually would filter down to every officer and employee of the hospital. Then we would have real hospital social service.

This is not an altogether visionary conception. The change is even now coming about in many of our hospitals through the influence of live social service departments. At first people are a little sceptical, but very soon as the benefits of the work are shown they begin to cooperate heartily and gradually, almost insensibly, a new spirit is felt throughout the whole place. This educational work of the social service department is not the least of its many beneficent activities.

To summarize the arguments for hospital social

service: It is a logical extension of modern hospital treatment, demanded by our higher standards of economy and efficiency, by our developing ideals of social responsibility and humanity, and by the new demands of preventive medicine as well as of medical diagnosis and treatment. It directly and remotely benefits the patient, the family, the community, the hospital and the professional worker. It is universally commended wherever it has been tried, and—it works.

A STUDY OF THE BACTERIEMIA IN PNEUMOCOCCUS INFECTION OF THE RABBIT.*

By G. A. RUECK, M.D.,

NEW YORK.

Following intravenous inoculation with the pneumococcus the rabbit develops a bacteriemic infection. From this recovery may take place, but usually it is fatal. During the course of these pneumococcus infections and at autopsy pneumococci are always present in the blood, but they vary greatly in number. The conditions determining these fluctuations in the number of pneumococci and other bacteria in blood infections have never been clearly understood.

Wyssokowitsch observed, 26 years ago, that bacteria injected intravenously are not physiologically excreted in the urine[1] and feces, although they disappear rapidly from the blood. Rolly[2] and Roloff,[3] however, found organisms in urine when there was no evidence of lesion of the kidney. The presence or absence of minute lesions is of course difficult to exclude or to demonstrate. After the blood cultures had become sterile Wyssokowitsch found living organisms in the liver, spleen, and bone marrow, and considered the organs bacterial filters; in short, the battlefield of the struggle between the organic cells and the bacterial invaders. It depends upon the outcome of this struggle, he said, whether or not infection will take place. After the discovery of the bactericidal power of the blood serum Wyssokowitsch's observations were attributed to the combined activity of the organs and the blood. But other observers found that the blood lacked bactericidal action on some bacteria. Thus Behring and Nissen,[4] and Kruse and Pansini[5] long ago found that pneumococci grew rapidly in the blood sera of both normal and immunized animals. Similar observations have since been recorded by Weil[6] in his experiments with the streptococcus. He injected rabbits with the streptococci isolated from cases of scarlatina, and, for purposes of comparison, other rabbits with *B. typhosus* and *B. subtilis*. Blood was drawn from the jugular vein at certain intervals, and plated in agar for counting. A portion of blood drawn from the jugular vein of each rabbit soon after the inoculation was defibrinated and incubated at 37° C. in test tubes. A certain amount of this incubated blood was plated in agar whenever a new blood culture of a rabbit was made. In this way he compared *in vivo* and *in vitro* the action of the blood on the streptococcus, and on the two organisms used as controls. In the living animals Weil[6] found shortly after intravenous inoculation first a decrease and then an increase in the number of bacteria injected. Later they again diminished in number. The animals finally became emaciated, had diarrhea, and died of paralysis. In only a few animals was an increase in the number of bacteria found before death. But when infection was rapidly fatal there was after the initial decrease a progressive increase of bacteria. In the defibrinated blood which he incubated *in vitro* the bacteria grew. The normal rabbit serum, Weil assumed from his experiments, is without any means of defence for all bacteria, because the number of bacteria *in vivo*, after the initial decrease, increased again as soon as the filter effect of the organs ceased, and because the blood incubated in the test-tube did not hinder the growth of the bacteria. The antibacterial reaction noticed in the body of an animal in the course of an infection cannot, according to Weil, be attributed to the known means of defence of the blood of ordinary laboratory animals, but is due to some unknown vital function of the body acquired during infection, and ceasing to act as soon as the blood leaves the body.

Of all the bacterial species the pneumococcus is perhaps the least susceptible to the bactericidal action of sera *in vitro*. And yet sera of some normal and many immunized animals have been shown to possess both lytic and opsonic action on this organism. Witness, for example, the studies of Bezançon and Griffin,[7] Neufeld,[8] Wadsworth,[10, 11, 12] and others with agglutinins and precipitins; the observations of Radziewsky,[13] and of Neufeld with lysins, and the studies of Neufeld and others on opsonins. Witness also the more recent work of Wadsworth on the action of immune sera on the pneumococcus, both in vitro and in pneumococcus infection of the rabbit and dog, from which it appears that bactericidal action may be present in rabbit serum when tested with the pneumococcus, even if this is incomplete and followed by growth.

That an elevated temperature may be inhibitory to the multiplication of bacteria is suggested by the recent study of the thermal limits of growth of bacteria in culture, of the increased activity of immune sera at elevated temperature, and of the effect of hyperthermy on infection in animals. Sulina[14] and others studied the thermal limits of bacterial growth in test tubes, and concluded that the growth of bacteria in the infected animal body must, in approximately the same way, be inhibited through an elevation of body temperature.

That the increase in body temperature may retard the development of infection is shown in Filehne's[15] experiment Animals were inoculated with streptococci which he isolated from cases of erysipelas. The inoculated animals when kept warm were only moderately sick, and recovered. Controls untreated died. Pasteur, Joubert, and Chamberland[16] found that anthrax cultivated at 41.5° C. lost its virulence. Hens and pigeons, which normally have a body temperature ranging above 41° C. only when chilled, became susceptible to anthrax in their experiments. K. Wagner,[17] by decreasing the temperature of inoculated hens with antipyrin or exposure to cold obtained similar results. Pasteur and many others have found pigeons and other birds insusceptible to pneumococcus. Recently in the experiments of S. Strouse the pigeon was made susceptible to the pneumococcus when its temperature was lowered by injections of pyramidon. Walther[19] was among the first to suggest the beneficial effect of an elevated temperature upon the course of pneumococcus infections in rabbits. He incubated three rabbits at 35 to 38° C. immediately after inoculation with the pneumococcus. Two animals were

*From the Department of Bacteriology, College of Physicians & Surgeons of Columbia University, New York City.

incubated 14 hours after the inoculation. Every 3 to 4 hours the rabbits were taken out of the thermostat and cooled off at room temperature. During incubation the body temperature of the rabbits rose from 41° C. to 42° C. Control animals similarly inoculated were kept at room temperature. The three animals incubated immediately after inoculation died, but they outlived the controls kept at room temperature. In one instance the incubated rabbit lived three days and nineteen hours, and the control animal only nineteen hours. He concluded that the artificial elevation of the body temperature of the infected animal retarded the multiplication of the bacteria. The rabbits which were incubated fourteen hours after the inoculation died almost as soon as the control animals. At autopsy he found pneumococci in large numbers in the blood and tissues of the control animals, and in those incubated fourteen hours after infection, but very few in those incubated early. In the animals incubated fourteen hours after inoculation, he said, the pneumococci had enough time to multiply and weaken the organs and tissues so that an elevation of temperature was of no help to them in their fight with the bacteria.

Rovighy,[20] Löwy, and Richter,[21] Kast,[22] Welch and Sirotinin, Sulina and others obtained results similar to those of Filehne and Walther in their experiments with other bacteria by elevating the body temperature of the infected animal. In these experiments, however, the effect of an elevated body temperature on leucocytosis or in stimulating the different protective activities of the blood serum was not studied. Rolley and Meltzer,[23] Lüdke[24, 25, 26, 27] and others have demonstrated experimentally that an elevation of the body temperature of animals increased the agglutinative, hemolytic, bacteriolytic and complementary activities of blood sera tested *in vitro*. The writer[28] also has found that an elevation of the body temperature experimentally induced by the incubation of animals increased the opsonic activity of the blood serum in normal, immunized and infected rabbits. In Sulina's studies phagocytosis in vitro was most active between 39° C. and 40° C.

Although in Neufeld's and in Wright's[29] experiments the leucocytes of normal and immunized animals were seemingly equally phagocytic, Rosenow,[30] and Potter and Krumweide[31] observed that the leucocytes in pneumonia have a greater phagocytic power than in health. Shattock and Dudgeon[32] found that washed pneumonia leucocytes were more phagocytic in pneumonia serum than normal leucocytes, whereas in puerperal streptococcus infection the patient's leucocytes were less active as phagocytes than those of healthy persons in the same serum.

In all the above-mentioned work evidence of the conservative action of fever was obtained. A few investigators, however, found in their experiments that an elevated body temperature predisposed or injured the animal, and thus favored the course of the infection, as in the studies of Ritzmann,[33] and also Barankeiff.[34] Lüdke found that clinically in man the most favorable time to demonstrate bacteria in the circulating blood is the time when the body temperature is most elevated, that with the decrease of the temperature the bacteria decrease and that with the disappearance of the fever bacteria are almost always absent in the blood. In order to study more fully and experimentally on animals these relationships of the bacteriemia to the fever I have made the following study of the bacteriemia and of the fever in pneumococcus infection of the rabbit.

The pneumococcus was chosen because it is very susceptible to elevations of temperature when grown in culture, and because it gives rise to a purely bacteriemic infection in rabbits. A pneumococcus was isolated from the sputum of a pneumonia patient.* Rabbits were inoculated with this pneumococcus in one ear vein, and blood for culture was drawn at stated intervals from the vein of the other ear. This blood was plated in dilutions,† and counts were made of the colonies to determine the number of pneumococci present. Morphological preparations were made from the colonies, but their characteristic greenish color and halo easily distinguished the pneumococcus colonies. Contamination, however, was exceptional. Rapidly fatal infections after small and large doses of the pneumococcus, and less virulent infections, fatal only after several days of fever, were all studied. A limited number of inoculated animals recovered spontaneously or after treatment. These were also under observation.

The rabbit infections were studied in series or in sets of one to six animals. In all, 42 rabbits were under observation. These fall into two groups: (1) The group of rapidly fatal infections, 25 rabbits. (a) Without initial decrease of bacteria, 20 rabbits. (b) With initial decrease of bacteria, 5 rabbits. (2) The group of prolonged infection, 17 rabbits; (a) of which 9 were fatal; (b) and 8 recovered. The 20 rabbits of group 1 (a) died rapidly within 18 to 48 hours after inoculation. The bacteria increased continuously after inoculation until death of the animal. An initial decrease of bacteria was noticed in none of these animals. An increasing temperature accompanied an increasing bacteriemia from the start in ten of the rabbits. In one of the ten remaining rabbits the temperature increased only 2°; in another it did not increase; in five others the temperature fell 2/10 to 1 2/10° C. In the remaining three rabbits of the set there was, one hour after inoculation, a slight decrease of temperature followed by an increase which was highest at the end of the second day. An antemortem drop of temperature took place in only three rabbits of this entire group. A high temperature accompanied by a retardation in the growth of bacteria was not found in any rabbit of this group. Neither rise nor fall of temperature had any apparent effect on the bacteriemia in these animals.

The five rabbits of group 1 (b) died within two to two and a half days after inoculation, and thus outlived slightly the animals of the previous group. In all of these a marked initial decrease of bacteriemia within two and a half to six hours after inoculation took place. This initial decrease was followed by a continuous increase of bacteria until death in two rabbits. There was a second single remission in the number of bacteria in the three other rabbits. The temperature, contrary to that of the first group, rose in all these rabbits with the increasing bacteriemia, and reached its maximum at the end of the second day (104.4, 105, 105.6, 106.6, 105.2, 105). An ante-mortem fall of temperature was noted in three rabbits, but the other two rabbits of this set died during the night, and the tem-

*Encapsulated gram positive streptococci of characteristic morphology which fermented inulin, which gave a characteristic reaction on blood agar plates, and were dissolved by rabbit bile in dilutions of 1:20 were considered pneumococci.

†Colonies of the pneumococcus develop well in blood agar, but if the blood is too highly diluted many of the pneumococci fail to develop in agar plates. I usually used /10 or 1/20 c.c. of blood for plating.

perature records were incomplete. In these rabbits a temperature above 104° F. at the end of the second day was accompanied in some instances by an increase, in other instances by a decrease in the bacteriemia. The protective activity of the body cells and of the blood of the rabbit against the invading bacteria was indicated by the initial decrease of bacteria in all rabbits of this group. Later a rise of temperature above 104° F. was accompanied by a marked decrease in the bacteriemia at the close of the second day in three animals and by a slight increase in the other two. Ante-mortem in the rabbits dying with a high temperature the increase of bacteria was relatively slight, whereas in those dying with a low temperature the increase of bacteria was exceedingly marked.

Of the 17 rabbits of group 2, the group of prolonged infections, 9 died within 3 to 7 days, and 8 recovered. Each of the first 11 rabbits of this group is a separate experiment, and requires separate consideration. All of these received intravenous inoculations of a pneumococcus culture (W) which under artificial cultivation had lost most of its virulence. Beginning with the first rabbit which received 4½ c.c. the other rabbits in series received smaller and smaller doses as the organism regained its virulence. Six rabbits of another experiment which had been inoculated intravenously by a usually fatal dose of a pneumococcus culture recovered. They were studied here only for the purpose of determining the time during which pneumocci might be found in the blood after the temperature had become normal.

Rabbit 2 was inoculated with 4½ c.c. of a 48-hour broth culture of an attenuated pneumococcus W. The temperature rose from 98° to 100.4° within one hour and to 104.5° within six hours after inoculation. During this period the bacteriemia decreased from 2,340,000 to 80. The second day the temperature fell 4½° and then toward evening rose again 2½°. The bacteriemia had increased from 80 to 410 and toward evening to 24,115. Then al elevated temperature of 103° to 103.5° persisted for 30 hours. During this time the bacteriemia fell from 24,115 to 16,298, then increased to 47,462 and fell again to 9,646. The fifth day, antemortem, the temperature fell from 103° to 98.6° and the bacteriemia increased immediately, rising in 16 hours from 9,686 to 75,600, and then 8 hours later the pneumococci were innumerable at autopsy.

In rabbit 3, following inoculation of 3 c.c. of a 24-hour rabbit-serum broth culture of pneumococcus W., the temperature rose in 6 hours to 104.6°. During this period the bacteriemia was one hour after inoculation, 7,897, and decreased in 2½ hours to 1,829 and in 6 hours to 130. The second day the temperature fell 2½°, then during the evening and night rose again 2°; the bacteriemia increased from 130 to 6,731 and later to 49,280 with the rise in temperature. The animal took food and appeared well. The elevated temperature, 103°-104°, continued 24 hours, and the bacteriemia fell from 49,820 to 3,896. On the fourth day, a Sunday, there were no observations. The fifth day, antemortem, the temperature fell to 98.8°, the bacteriemia increased from 3,896 to 317,364 per 1 c.c. of blood and at autopsy the pneumococci in the heart's blood were innumerable.

Rabbit 10 was inoculated in the late afternoon with 1/10 c.c. of a virulent broth culture of pneumococcus W. which had been incubated only 5 hours and therefore contained relatively few pneumococci. The temperature remained unchanged after inoculation but the next morning it was 105.5°. The bacteriemia increased from 830 to 2,710 during the first hour after inoculation but the next morning, with the rise of temperature, it had fallen to 1,000. The second day the temperature rose from 104.5° to 106°. The bacteriemia increased from 1,000 to 5,340 the evening of the second day, and was 9,063 in the morning of the third day. Then it dropped suddenly in 8 hours to 955, the temperature continuing elevated. The fourth day, antemortem, with a temperature falling to 98°, the bacteriemia increased to 1¼ million per 1 c.c. of blood.

Rabbits 12, 13 and 14 were inoculated intravenously with .01 c.c. of a 24-hour broth culture of a virulent pneumococcus W.

In rabbit 12 the temperature rose only .5° F. within the first 6 hours. The bacteriemia increased from 9,752 to 80,136 six hours after inoculation. The second day the temperature ranged from 103° to 105° F. The bacteriemia decreased at the same time from 80,136 to 30,528, then increased over night to 905,824 per c.c., the temperature falling from 105° to 103.5°. The third day, ante-mortem, the temperature was 104° to 104.5°, and fell abruptly over night to 99.5°. At autopsy the plates of blood in dilution were too crowded with colonies.

In rabbit 13 the number of bacteria in 1 c.c. of circulating blood one hour after inoculation was 40. Six hours after inoculation the blood culture was sterile. The temperature decreased during the first six hours from 100.6° to 98.4°. The morning of the second day the temperature was 103.4° and the bacteriemia 8,454. The temperature fell during the day to 101.5° and the bacteriemia rose to 32,895. The morning of the third day the temperature was 102.2° and it rose in the afternoon to 104.5°. The bacteriemia decreased from 32,895 to 3,922 in the morning, and continued low—the evening count being 4,664. The fourth day, ante-mortem, the temperature fell to 101° and 101.3°. The bacteriemia increased from 4,664 to 20,670 and to 45,792. At autopsy the colonies in the plates of blood in dilution were too numerous to count.

In rabbit 14 six hours after inoculation there was a marked increase of the bacteria from 11,819 to 60,314, and the temperature rose from 101.2° to 104°. The second day the temperature continued elevated, 103.6°, 105° and 104.6°, and the number of pneumococci decreased from 60,314 to 8,904 in the morning and 6,784 in the afternoon. The third day the temperature fell sharply to 98.4° over night, but the bacteriemia increased to 101,396. In the afternoon of the third day the number of pneumococci decreased from 101,396 to 8,480, although the temperature was only 101°. The fourth day there was a marked ante-mortem increase of bacteria to 562,860, and only a slight rise of temperature to 101.6° and 102°. At autopsy the plates of diluted blood were too covered to count.

Rabbits 22, 23, 24 and 25 were all inoculated intravenously with 1/100 c.c. of a 24-hour growth of pneumococcus W. in rabbit serum broth. Rabbit 22 died early and was recorded in the group of rapidly fatal infections.

In rabbit 23 there was only a small number of pneumococci, 20, in the circulating blood, two hours after inoculation. The temperature rose slightly from 99.6° to 101.4°. Six hours after inoculation the bacteria increased from 20 to 70 and the temperature .2° F. The morning of the second day the temperature was 100.5°, and the blood culture sterile. The afternoon blood culture was again positive, giving a count of 180; the temperature having risen to 103.4°. The third day there was a moderate increase of bacteria from 180 to 255 and 760 and a temperature of 102.8° in the morning and 104° F. in the afternoon. There were no observations on the fourth day, a Sunday. The fifth day the morning temperature was 101° and the bacteriemia 1,540. The evening temperature fell to 98.4° and the bacteriemia increased from 1,540 to 9,911. The sixth day the temperature was normal, 101° to 101.2°, the animal appeared well; no cultures were taken. The seventh day the morning temperature was 90.4°, and the number of bacteria 5,353. The temperature continued to decrease and was in the evening 98.2°. The bacteriemia increased with the falling temperature to 10,229. The eighth day, antemortem, the temperature was 97.2° and the bacteriemia 9,874. In the afternoon the temperature rose to 102° and then decreased to 100°. The bacteriemia fell from 9,874 to 100 a half hour ante-mortem.

Comment: During the first four days the fluctuations in temperature and bacteriemia were unimportant as compared with the bacteriemia in the other animals. Both temperature and bacteriemia were slight during this period and gradually increasing. During the last four days of infection the bacteriemia was more marked, but the animal did not respond by an abnormally elevated temperature, on the contrary, with the increase in bacteriemia there seemed to be an exceptional depression of temperature. The animal was emaciated during the last four days and so possibly unable to respond. Nevertheless, at the same time, it had evidently developed sufficient immunity during the first four days to inhibit the bacteriemia and to prevent the marked increase usually noted ante-mortem.

In rabbit 24 the bacteriemia, two hours after inoculation, was 80,510 six hours after inoculation and 3,367 the next morning. The temperature rose gradually from 99.6° to 101.6°, and was 104.2° in the morning and 104.6° in the evening of the second day, the bacteriemia having increased by evening to 47,664. The morning of the third day the pneumococci had increased to 135,680, the temperature continuing elevated, 104.2°, and in the evening 104.6°. This

continuously high temperature of the third day was accompanied by a decrease of the pneumococci from 135,680 in the morning to 7,473 by the evening of the third day. Temperature and bacteriemia of the fourth day, a Sunday, were not recorded. The fifth day the animal was weak and exhausted. The temperature had fallen to 98.4° in the morning and 97° in the evening, and the bacteria had increased from 7,473 to 22,843 and the colonies of the blood culture in the evening of the fifth day were too numerous to count. The rabbit died over night.

In rabbit 25, the number of bacteria in the blood two hours after inoculation was 200, and six hours after inoculation, 120, increasing over night to 2,120. The temperature rose at the same time from 102.2° to 103.6°. The second day the temperature reached 104.6°, and the bacteriemia fell in eight hours from 2,120 to 370. The temperature continued elevated the third day, rising to 105° and then fell sharply 2° in three hours without change in the bacteriemia. Counts of 370 and 310 per 1 c.c. of circulating blood were obtained during the day. There were no observations on the fourth day, a Sunday. The morning of the fifth day the animal was very weak, exhausted and dying. The temperature fell to 101.2° and a blood culture taken immediately before death showed an enormous increase of bacteria, the plates were too crowded to count.

In the group of prolonged infections 8 rabbits recovered from the pneumococcus bacteriemia.

Rabbit 1 was inoculated intravenously with 3 c.c. of a twenty-four-hour broth culture of pneumococcus W., containing 70,000,000 of pneumococci in 1 c.c. The cultures made one-half, one and two hours after inoculation contained innumerable pneumococci. The temperature increased slowly but continuously from 99.8° in the morning to 104.8° in the late afternoon. In the fourth culture, taken in the afternoon, 10,800 pneumococci per 1 c.c. of blood were found. Over night the bacteriemia increased to 36,199. The temperature continued elevated the second day, 104.4°, 103.6° and 105.6°. The bacteria decreased from 36,199 in the morning to 24,751 in the evening. The animal was very sick. No observations were made on the third day, a Sunday. The fourth day the temperature was 103.6° in the morning and the pneumococci only 365 per 1 c.c. of blood. They decreased to 70 in the evening and the temperature fell to 101.8°. The morning of the fifth day there was a brief rise of the temperature to 104.6° followed immediately by a fall to 100° F. The bacteriemia decreased to 25 per 1 c.c. of blood and the afternoon culture was sterile. The sixth and following days the temperature was normal and the blood cultures sterile. Although records are lacking the third day, it is evident that this animal recovered by crisis.

The nineteenth rabbit, a male, weighing 1,238 g., also recovered. It was inoculated withit 1/100 c.c. of a twenty-four-hour rabbit serum broth culture of a pneumococcus having passed through rabbit 13.

First period: The number of pneumococci in 1 c.c. of circulating blood two and one-half hours after inoculation was 20 and six hours after inoculation 80. The temperature rose from 98.6° to 104° within the first six hours. Second period: Next morning the temperature fell to 102° and then rose to 103°. The bacteria increased to 110 and then to 170 per 1 c.c. of blood. In the morning of the third day the temperature was 102.5° and a sterile blood culture was obtained but pneumococci were still present as the following positive blood cultures proved. In the evening of the third day there was an increase of pneumococci to 100 per 1 c.c. of blood and a rise of temperature to 104.8°. The morning following this high evening temperature of the third day 40 pneumococci per 1 c.c. of blood were found. The temperature fell to 102° then rose to 105° and fell again to 103°. These fluctuations in tempeature were followed by a further decrease of bacteria to 4 per 1 c.c. The fifth day the temperature was normal. The morning blood culture was sterile, but 15 pneumococci per 1 c.c. of blood were found in the evening blood culture. Third period: From the sixth to the thirteenth day after inoculation the temperature was normal, fluctuating from 100.6° to 102.4°. A few pneumococci were found in the blood up to the thirteenth day after the inoculation, although the animal was apparently well. This infection is therefore an example of a latent microbism or harmless parasitism.

This rabbit belonged to a set of rabbits which were all similarly inoculated; the others died early. The effect of the inoculation differed with each animal and more markedly than in any of the other sets of animals studied. For comparison the results of the first six hours of observation are here tabulated:

Number of Rabbit	Weight in Grams	Temperature Before Inoculation	Two Hours After Inoculation		Six Hours After Inoculation	
			Temperature	Number of Pneumococci per 1 c.c. Circulating Blood	Temperature	Number of Pneumococci per 1 c.c. Circulating Blood
16	1283	100.2°	100.6°	63	103.°	35,404
17	1230	98.8	99.6	7291	103	Too many to count
18	1465	100	99.8	636	103.2	91,584
19	1238	98.6	100.4	20	104	80
21	1220	100.6	100.8	6042	103.8	Too many to count

The marked variation in the bacterial counts of the bacteriemia after inoculation of these animals is an indication of the different degrees of resistance in the rabbits, which does not depend on the size or appearance of the animal.

Since in moderately virulent and prolonged infections many of the inoculated bacteria are immediately destroyed by the blood and other tissues, and since this destruction varies greatly with the resistance of the different animals, it is impossible to determine the number of pneumococci inoculated in a suspension by means of blood cultures taken after inoculation.

In the course of these prolonged infections three periods were recognized. First, an initial period of injury and disturbed balance immediately after inoculation. This was characterized by a decrease* in the number of bacteria in the blood within the first six hours after inoculation, and by a rise of temperature in all these rabbits. The initial decrease in the number of bacteria in these prolonged infections might be attributed to the bacteriolytic action of the blood, or to other activities of the protective mechanism in these rabbits, or to lack of virulence in the pneumococcus; but there is no evidence that the rise of temperature following the inoculation was an important factor. The initial decrease in bacteremia preceded the rise of temperature. Second, there was a variable period of two to six days during which the factors of resistance of the animal and the bacterial virulence were more evenly balanced, and both temperature and bacteriemia fluctuated. The elevation in body temperature was sustained and ranged in general from 103° to 106°. In a few instances it fell to normal in its fluctuation. The ba cteriemia in all the rabbits of this group after the initial decrease increased. This increase was followed by a second marked decrease, and then by a second increase, which continued until death in eight of the nine fatal cases. In one fatal case, 23, the bacteriemia decreased ante-mortem. In the cases which recovered the second rise in the bacteriemia was followed by a fall and recovery. The pneumococci persisted seven days in one instance, but in the seven other animals disappeared in 24 hours.† The increase after the initial decrease of pneumococci may be attributed to the fact that the pneumococci surviving the initial destruction by the tissues become adapted to the new conditions, and multiply in some animals more rapidly than in others. Their toxic products acting on the tissues of the rabbit cause a rise in temperature and the

*In seven rabbits this decrease was marked. In four the number of bacteria in the culture inoculated was not determined.

†Wolf and Wadsworth have also noted instances of this harmless parasitism of the pneumococcus following recovery from pneumococcus infection.

formation of antibodies, a certain degree of immunity. The second decrease in the number of pneumococci might be more reasonably attributed to the action of this immunity than to an elevated temperature which of itself seemed to have little or no influence on the multiplication of the pneumococci. From the data of these experiments no definite relationship could be established between the rise of temperature and the fluctuations in the bacteriemia during this period.

Finally there was the period of disturbed balance, ending in death or in recovery of the animals. During the prostration, in 8 of the 9 fatal cases of this group of animals, the bacteriemia increased enormously, and the temperature fell abruptly. The resistance of these animals was exhausted, and the tissues were no longer able to react. The relationship of the increase in bacteriemia and the fall in temperature was a similar and constant one in all the animals. In one rabbit (23) after a more prolonged infection, conditions were reversed; the bacteriemia decreased markedly ante-mortem, and the body temperature of the animal increased 3° from subnormal to normal, which was sustained until death. As pointed out above, this was evidently due to the immunity acquired during the long course of infection, which was sufficient to inhibit the development of the bacteriemia. Although apparently an exception, rabbit 23 is after all only an additional example to the fact that the temperature in itself is of secondary importance, inhibiting the multiplication of the bacteria in the animal body when there is considerable resistance or immunity present in the tissues.

Summary.—From my experiments it is evident that the course of pneumococcus infections varies greatly even in the rabbit, although equal doses of the same organism are used. The rabbit's tissues, therefore, have some anti-bacterial properties. Large doses of the pneumococcus cultures or the more virulent pneumococci neutralized these anti-bacterial substances in the body tissues of the rabbit, and the bacteriemia progressed immediately to fatal issue. The temperature may rise, or it may fall, but this apparently had no effect on the bacteriemia in these animals. Moderate doses or less virulent pneumococci give rise to a longer course of infection, with fluctuating bacteriemia and temperature. These prolonged infections are also often fatal, but occasionally recovery takes place. From the data of my experiments with virulent and with prolonged infections there was no very definite evidence of a retarding influencce of an elevated temperature upon the growth of pneumococci in the rabbit. A temperature of 105° to 106°, which retards or arrests pneumococcus growth in the test tube and which may also inhibit growth in the rabbit's tissues, does not necessarily diminish the bacteriemia

In conclusion I wish to acknowledge my indebtedness to Dr. Augustus Wadsworth for his advice and help in preparing this paper.

A NEW METHOD FOR DETECTING OCCULT BLOOD IN GASTRIC CASES.*

BY ARTHUR L. HOLLAND, M.D.,

NEW YORK.

ASSOCIATION VISITING PHYSICIAN, CORNELL UNIVERSITY MEDICAL COLLEGE CLINIC, NEW YORK CITY.

THE diagnosis of gastric carcinoma or gastric ulcer, to be of any value, must necessarily be made early. Clinicians of experience are aware of the difficulty of attaining this end. Without bringing to bear all

*Gastroenterological investigations in the Department of General Medicine.

means at our disposal, early cases, that might otherwise receive the benefits of appropriate medical or surgical treatment, are sacrificed or allowed to advance perilously near the danger point. The present report will not deal with the various methods of diagnosis, but will be confined to one test, that in the writer's hands has recently yielded results that are at least interesting.

There are several tests for occult blood which are used in routine practice. The following are the best known and are perhaps the most reliable: The benzidin test, as modified by Schlesinger and Holtz, the aloin and the guaiac tests. The modified benzidin test above mentioned, has recently attained considerable vogue. To be of value such a test should be sensitive, as beginning ulcers or new growths rarely breed to any large extent. On the other hand, by reacting to the small amounts of blood that have been swallowed from the nasopharynx, spongy gums, or that which is incident to the passage of the stomach tube, the sensitive test defeats its own ends.

At the Cornell University Medical College Clinic, where the writer sees most of the stomach cases and is personally responsible for the gastric analyses, the technique employed in securing the gastric contents is most carefully arranged in order to exclude so far as possible these sources of error. Very soft tubes of the Delafield type are used; no aspirating or pumping is employed and patients are cautioned not to strain unduly in expressing; considerable time being allowed for syphonage. No effort is made to secure a large return; only sufficient contents are withdrawn to make the ordinary acid calculations and the microscopical examinations. The total residue is estimated from the acidity of a measured washing, according to the Mathieu-Rémond method. Notwithstanding these precautions, occult blood was found in 27 out of 128 analyses. While all these were straight stomach cases, having been referred after other diseases were excluded, this figure is ridiculously high and well illustrates the fact that such tests are worthless except in a negative way, and there is but little comfort even in this conclusion, for one is not infrequently disappointed in not finding blood where the clinical findings and subsequent behavior of a case would lead one to expect a positive reaction.

That he might obviate these objections to the blood tests at our disposal the writer has evolved a technique that so far as it has been used has proved sufficiently sensitive to ulcerative conditions within the stomach, at the same time eliminating all sources of blood outside that organ.

The patient is directed to present himself in a fasting condition. His throat is sprayed with a bland neutral oil. Only those patients who have become used to the tube after one or two previous examinations are used for the test. A very soft closed-end Delafield No. 30 French tube is gently passed, the patient sitting on a low backless stool. The stomach is then subjected to a thorough lavage with tap water. This lavage is continued until the returned water is clear and free from particles of mucus or other material. As a rule considerable swallowed mucus is encountered in the fasting stomach. This in the writer's experience is the greatest source of error in the ordinary tests, as most of it originates in the nasopharynx and contains sufficient blood to give a positive reaction. The stomach being clean all of the water is syphoned off. Two hundred cubic centimers of a 1 per cent. solution of hydrogen peroxide are then introduced. The operator now stands at the patient's right side with his left arm about the patient's neck and holds the tube between the fingers of the left hand close to the patient's teeth to prevent it from being vomited or pulled out. With his right hand he holds aloft the funnel end of the tube. The patient is now directed to lean back until the body is in a horizontal position. This position is maintained for one or two minutes to allow the peroxide solution to thoroughly bathe all parts of the stomach. It must be remembered that most ulcers and new growths are situated near the pylorus or on the lesser curvature. The solution is carefully syphoned off and tested in the following manner:

The entire specimen is placed in a narrow graduate and allowed to stand for several minutes. This is to give the gas bubbles time to rise to the top, carrying with them the disintegrated pus or mucus with the blood that the solution may have collected from a possible ulcerating surface. The top 50 c.c. are then drawn off and placed in a small Erlenmeyer flask and well shaken. To this are added 20 drops of a solution of benzidin, freshly made by dropping 1 decigramme of benzidin in 3 c.c. of glacial acetic acid. A green color appearing within one minute indicates a positive reaction.

In 20 analyses the following results have been obtained: Nine analyses in cases that had, by other methods, shown occult blood where the clinical findings indicated neuroses or mild disturbances of digestion, were negative.

Six normal individuals were negative.

One apparently normal individual was positive. (This patient had never had a tube passed before and it was not possible to clean out the stomach as thoroughly as it might have been.)

One patient whose case had been diagnosed repeatedly as gastric ulcer, but in whom an impacted gallstone was subsequently found on operation, was negative. (The test was given to this patient on two occasions so sure was the writer that he was dealing with an ulcer.)

Two cases diagnosed clinically as ulcer were positive. (Both of these cases gave straight ulcer histories with the characteristic pain one-half hour and two hours after eating and on examination the localized tenderness of ulcer was found in each.)

One case of alcoholic gastritis, with a history of recent vomiting of blood, was positive.

The writer, realizing that reliable deductions cannot be drawn from a series of such limited proportions, is offering the above merely as a preliminary report to be followed later by a more comprehensive paper, should the results of investigations on a larger series warrant it.

A METHOD OF PREPARING NERVE TISSUES FOR MICROPHOTOGRAPHY.

By H. A. SIMS, M.D.,

MONTREAL.

CLINICAL ASSISTANT IN NEUROLOGY, ROYAL VICTORIA HOSPITAL.

The difficulty of obtaining a stain for nervous tissue which will not only give a complete picture of the section to be examined, but will also afford a clear-cut definition of the individual cells, suitable

(From the Pathological Laboratories of the Royal Victoria Hospital, Montreal, under the direction of O. C. Gruner, M.D.)

for microphotographic reproduction, has led me to formulate the technique described below.

The ordinary silver impregnation methods are not applicable to morbid tissues by reason of their faculty for picking out only occasional cells in great detail. In my hands at least, that of Levaditi, and the commonly used iron and alum hematoxylin methods do not give a sufficiently clear picture of the entire field. This is doubtless due to the well-known slowness with which both staining and differentiating processes take place in nervous tissues, the result being a too diffuse impregnation of the tissue-elements.

The method with which I first attempted to overcome the difficulties named was suggested to me by Dr. Gruner, who received it as a tradition years ago. The originator of the process appears to be unknown.

It is as follows: By adding a saturated alcoholic solution of hematoxylin (at the moment of staining) to a two per cent. solution of iron-alum in distilled water, in the proportion of one drop of the hematoxylin solution to each cubic centimeter of the iron-alum, a lake is formed. The slide is covered with this lake, which is allowed to stain for from thirty seconds to three or five minutes at room temperature. The slide is then washed in running water. A few drops of one per cent. acid alcohol are run quickly over the slide and washed off, followed by the Van Gieson stain, which is also washed off almost immediately. Clear and mount. (The Van Gieson is used solely to sharpen the picture and darken the iron, as a counterstain is unnecessary.)

While this method was a great improvement on any others yet tried, it also gave too great diffusion when applied to nervous tissue, and while this could be avoided to a great extent by lengthening the period of staining and differentiation, absolute clearness was not obtained. After several modifications of the above method had been tried, the following was found to give the desired result (use paraffin sections, five to six microns in thickness, the tissue having been fixed in fifty per cent. formalin):

1. Reagents: (*a*) Saturated alcoholic solution of hematoxylin. (*b*) Five per cent. aqueous solution of iron-alum. Make a lake as before, one drop of (*a*) to each c.c. of (*b*).

2. Stain for ten minutes at room temperature.

3. Wash.

4. Aqueous solution of lithium carbonate, until section becomes an intense blue black. (This makes possible the extreme differentiation of the next step and does away with the necessity of using the Van Gieson, which naturally cannot be applied for any length of time without the appearance of a certain amount of undesired contrast-stain.)

5. Instantaneous immersion in ten per cent. acid alcohol.

6. Wash, clear, and mount.

The above applies to sections of five or six microns; thicker sections require a longer differentiation in the acid alcohol.

Result: All structures show up sharply, with photographic clearness, against a white background. The nuclear chromatin of nerve and infiltrating cells, and the nuclei of blood-vessels, etc., have an intense deep blue-black color; cell bodies, granules, and the commencement of axones are steel gray.

While claiming no originality for the above method, I wish to submit this modification of it as having the following advantages:

1. Simplicity and constancy of results.

2. Flexibility. It may be used with any of the usual fixatives, and may be adapted to sections of varying thickness by simply increasing the time of differentiation. Also it ought very easily to be applied to general tissues, though here it is doubtful if it would be any improvement on the usual methods other than in its speed and simplicity.

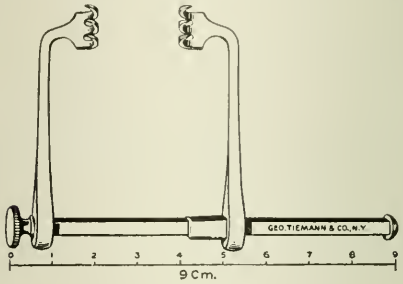
3. For microphotographic purposes and as a general stain for nervous tissues, it shows up all structures in the section, blood-vessels, meninges, and infiltrating cells, as well as the nervous tissue proper, more clearly and completely than any other process with which I am familiar.

SMALL SELF-RETAINING RETRACTOR FOR SUPERFICIAL DISSECTIONS.

By KENNETH BULKLEY, M.D.,

NEW YORK.

In performing office operations of various kinds in which good retraction of the superficial soft parts is helpful, I have had some difficulty in finding a mechanical assistant which fulfilled all requirements. The numerous small retractors of the spring type proved unsatisfactory because of the impossibility of varying the pressure of the spring. Those in which the spread is obtained by means of a thumb screw which on tightening causes the limbs of the instrument to describe the arc of a circle fail to give right-angled lateral pressure. The various instruments which require the operator to use the little finger in a ring to maintain traction have the obvious drawback of not allowing him the free use of either hand.



The accompanying cut illustrates a simple retractor for which I claim no originality but much usefulness. In principle it follows the Gosset instrument which depends on friction-leverage for the maintenance of traction. The arm distal to the thumb screw moves on the horizontal bar, while the proximal limb remains fixed. By removing the screw all parts can be detached for cleaning. The limbs at maximum separation give an operative field 5.4 cm. in breadth. The instrument weighs but ¾ of an ounce and will be found of great help in the absence of an assistant in such procedures as the removal of subcutaneous dermoids, lipomata, and foreign bodies in the hand in excision of isolated tuberculous lymph nodes in the neck, and in the bloodless opening of infections of the tendon sheaths and fascial spaces of the hand where direct vision is essential. The instrument can be readily manipulated by lateral pressure at the base of the distal arm. Its light weight minimizes the tendency to pull out of the wound, and its small size keeps it out of the way of the operator.

Y-BACILLUS DYSENTERY IN INFANTS AND YOUNG CHILDREN.

It is ten years since Hiss and Russel differentiated a type of dysentery bacillus, the so-called Y-bacillus, which is distinct from the Shiga-Kruse organism on the one hand and the Flexner bacillus on the other. Little attention has been paid to the Y-bacillus, probably because of the close relationship to the Flexner group. The Y-bacillus is a non-motile, Gram-negative rod, presenting certain characteristic cultural aspects, and resembling the Flexner bacillus in fermenting mannite, but differing from this organism in not fermenting maltose and saccharose. The study of the pathogenic rôle of the Y-bacillus has recently received considerable attention, particularly in relation to two distinct epidemics of dysentery occurring among children in Düsseldorf and Berlin. Both of these epidemics are described in the *Festschrift* dedicated to Adolf Baginsky, and constituting the sixtieth and sixty-first volumes of the *Archiv für Kinderheilkunde*. An elaborate study of the Düsseldorf cases was made by Bauer, Ellenbeck, and Fromme. The Berlin epidemic is described by Erich Siegel.

The occurrence of true dysentery in infancy is exceedingly rare. The diagnosis is generally based upon the presence of bloody and mucous stools, tenesmus, abdominal pain, and rapid prostration. Nevertheless the microscope has shown that bacillary dysentery may exist without the presence of the above severe symptoms. The difficulty in diagnosis is further increased by the close resemblance to bacillary dysentery which may be perceived in certain cases of follicular enteritis, typhoid fever, colicolitis, gastroenteritis, and dietetic disturbances of the intestinal tract.

The Düsseldorf epidemic of twenty-nine cases broke out in October, 1912, in the Evangelical Retreat and Hospital of that city, although it had been preceded by two obstinate cases of dysentery that had been observed during July and August in the same institution. Evidently these two cases provided the source of infection, for in two separate wards in which these children had been treated the affection suddenly and almost simultaneously appeared in a large number of other children. The source of the infection could not be discovered, although it was found that two-thirds of the nursing and other adult personnel of the hospital, while perfectly well, nevertheless yielded a serum that agglutinated the Y-bacillus. Noteworthy is the fact that the dysentery was of benign type, all of the children making an uneventful recovery, although in a few instances relapses occurred. Toward the end of the epidemic a number of adults, who gave a positive serum reaction, complained of abdominal pain, dizziness, and headache. They were mostly constipated, and only one of them, a nurse, developed the characteristic dysentery. Of 11 breast-fed infants in the institution at the time of the epidemic, none was affected. All of the 29 cases occurred in artificially fed infants less than two years of age. Only 7 of the cases were serologically negative. Some of the cases that gave a positive reaction presented no evidence of dysentery, indeed, appeared well and continued to gain in weight. Dysenteric stools were present in 11 of the cases. Four others showed a tendency to dyspeptic disturbances. Four of the patients had normal stools, though with an occasional admixture of mucus. The pronounced and characteristic cases of Y-dysentery began with mucous stools, which were followed by mucopurulent, and then by bloody stools. Marked restlessness was observed in all of the cases. Miliary nodules appeared in the skin in some of the patients, and in two of them there was a profuse morbilliform rash. A marked gain in weight preceded the onset of the symptoms in several of the cases. Most of the patients had no fever. The duration of the disease was from a few days to one or two weeks. No complications were observed.

Of considerable interest were the results of the bacteriological examination of the stools in these cases. In contrast to the constancy with which the specific microorganisms are obtained in the bacillary dysentery of adults, the Y-bacillus was isolated in only 7 out of 17 cases of frank clinical Y-dysentery in children. Thirty-six other children in the hospital were examined with reference to the presence of the Y-bacillus in the stools, and in two instances these microorganisms were detected, although the children were free from any clinical symptoms apart from a transient dyspepsia. Serological studies showed that a positive reaction is not present in all cases. A negative reaction is more apt to occur in children under six months of age, and occurs in about 7 per cent. of all cases in older children and in adults. The practical utility of the serological reaction is perceived in the fact that this enables one to determine whether the infection is caused by the Shiga-Kruse organism or by an organism of the Y and Flexner group.

The Berlin epidemic which is described by Siegel concerned a series of 9 cases that were admitted to the municipal Kaiser und Kaiserin Friedrich Children's Hospital during the summer and fall of 1912. In 8 of these cases the specific germ was isolated. In the remaining case the microorganism detected was the *Bacillus enteritidis* of Gaertner. In 8 of the cases bloody and mucous stools were present. The type of infection was a severe one, for half of the cases showing the Y-bacillus ended fatally. This epidemic furnished, therefore, a striking contrast to that which was observed in Düsseldorf almost at the same time.

One important point is emphasized by Siegel. Whereas Baginsky and Heubner question whether bacillary dysentery has pathologically anything in common with follicular enteritis, the microscopic examination of the intestinal mucosa in the fatal Berlin cases showed uniformly the same lesions as are present in the latter condition, namely, an hypertrophy of the solitary lymphoid follicles. Moreover, the clinical picture in both conditions is regarded as identical.

A NEW SIGN IN THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

The importance of the early diagnosis of pulmonary tuberculosis cannot be overemphasized. In this the physical examination of the patient takes precedence over laboratory methods particularly during the incipient stage of the disease, the time during which treatment offers the greatest hope of success. For this reason, whatever new clinical sign of early tuberculous involvement of the lungs is added to the few signs already available is to be welcomed and carefully investigated. For this new sign we are indebted to Professor Antonio Lombardi of Naples, who reports his observations in the *Giornale Internazionale delle Scienze Mediche*, August 31, 1913. The sign consists in the appearance of venous varicosities in the neighborhood of the spinous processes of the seventh cervical and of the first three thoracic vertebræ. These varicosities, which vary in length from one centimeter to one centimeter and a half and are of bluish color, are at times quite evident, and at other times are made visible by a gentle transverse stroking of the skin. They are observed most frequently in the neighborhood of the seventh cervical vertebra. They may be most minute; there may be only two or three of them, or there may be a large number of them. Occasionally in the region of the venous enlargements there may be a slight edema, and the patient may complain of tenderness in this region when it is pressed upon. This sign is especially to be observed in cases of pulmonary tuberculosis in which there is an infiltration of the apices, as revealed by supraclavicular and supraspinous dullness, diminished respiratory murmur, etc. It is present in from 88 to 90 per cent. of the cases, and has been denominated by Lombardi the "varicose zone of warning" (*zona varicosa d'allarme*).

Without going into the anatomical details which this observer points out in showing how an infiltration of the pulmonary apices leads to a venous engagement of the radicles in the above zone, it may suffice to state that these varicosities are of analogous origin to the enlarged veins that are irregularly distributed over the chest in cases of hypertrophy or congestion of the peribronchial glands, in asthma, in bronchitis, and in pulmonary emphysema, in which the left superior intercostal vein or its tributaries are pressed upon. In all of these cases, however, the venous enlargements are found chiefly in the lower part of the thorax, both in front and behind. Lombardi's sign appears most frequently in cases of disease of the right apex. Of particular value in diagnosis is the presence of this sign in children from five to ten years of age and in adolescents.

Oddities of Medical Nomenclature.

It is to be regretted that so little attention comparatively has been given by writers in the English language to the history of medicine, and especially to the life history and achievements of the great men in medical science. Little is known of some men who have blazed the way to the height to which medical science has attained. They have borne the heat and burden of the day and too often have been allowed to sink into oblivion. The deeds and lives of some of the pioneers of medicine provide an almost inexhaustible mine from which to dig rare jewels of facts and literature, a mine which is, comparatively speaking, untouched. The Royal Society of Medicine of England has taken a step in this direction by the establishment of a section of the history of medicine, and at the meetings of this section a fund of interesting and instructive information is tapped for the entertainment of the medical profession and of literary men in general. At a meeting of the section held early in the year, among other papers contributed was one by Mr. B. Glanvill Corney, dealing with some oddities in nomenclature. He said that in Rio de Janeiro during the epidemics of influenza, which occurred in 1777 and 1802-03, the disease was called "zamporinion" and "corcunda." He also referred to an epidemic of dengue which raged in Brazil in 1847 and was termed "polka" at Rio and "rabo aherto" at Bahia. The designation "zamporinion" was taken from the name of a Venetian singer who was popular at Rio at the time and had nothing to do with the Portuguese name for measles, sarampao, in Spanish sarampion. Corcunda meant hunchbacked and referred to the bent condition in which patients were left at the end of each paroxysm of cough, which was said to be of a very spasmodic character and closely to resemble whooping-cough. Dengue was termed "polka" after a distinguished court beauty at Rio, who was a native of Poland and was in great vogue at the time of the epidemic. The same epidemic received the name "rabo aherto" at Bahia because there chanced to be coincidently an unusual glut of the fish of that name. Corney likewise advanced the theory that an epidemic of cerebrospinal meningitis was coincident with the Bahia epidemic and that whooping cough played a part in the corcunda attack. He also alluded to the older folk names for influenza, "le tac," "the new delight," and the "jolly rant," which have in turn displaced each other and have themselves been replaced by "the flue." Although the paper on oddities in nomenclature is interesting rather than instructive, the establishment of a section of the history of medicine by the Royal Society furnishes an example to be followed. By such means concern in the doings and lives of the great men of science long dead is fostered and attention is directed to a branch of literature to which attention is surely due.

Treatment of Tetanus with Magnesium Sulphate.

The status of the treatment of severe tetanus appears to undergo rapid change from time to time. Some figures show that serotherapy possesses considerable efficacy; others show remarkable results.

from Baccelli's phenol therapy; still others show the promise of Meltzer's magnesium sulphate treatment. But many competent surgeons have reported total failure from all these methods, even when combined. We obtain the idea that locality and race must be reckoned with as well as the skill derived from long experience. It is claimed that among the Chinese recovery from tetanus is the rule, no treatment being employed. The remarkable results of Baccelli and his pupils cannot be duplicated outside of Italy. At a recent meeting of the Aertzlicher Verein of Wiesbaden (*Berliner klinische Wochenschrift*, August 25) Stadler asserted that the magnesium treatment when modified should be our chief reliance in the future. He would add to it Baccelli's phenol method, because of its remarkable showing, its rationale appearing to be that it suppresses the convulsions. Magnesium sulphate in solution injected into the spinal canal has the same tendency. Indeed so marked is the latter that if given in excess it may threaten the heart's action and respiration. The author found in the literature thirty-three cases treated with magnesium sulphate, with thirteen deaths. He himself has treated thus two severe cases and saved one. In discussion Weintraub considered along with the brilliant results on record the dangers of magnesium poisoning. He would not only inject calcium chloride in the muscles as an antidote, but also use camphor as a heart stimulant. Thus the magnesium and phenol treatment combined may come to supersede the older symptomatic resources (chloral, opium, and the specific treatment). The latter is still our prophylactic, but the profession does not seem to be aware that it is untrustworthy even in laboratory animals after tetanus is fully established.

News of the Week.

For Federal Medical Licenses.—Representative T. L. Reilly, of Connecticut, on September 27 introduced into the House of Representatives a bill providing for the issuance of Federal medical licenses which would permit those holding them to practise medicine in any State of the United States. The bill authorizes the President to appoint a United States Medical Licensing Board, to have headquarters at Washington, and to consist of two medical officers of the Army, two medical officers of the Navy, and two officers of the Public Health Service. The terms of the members of this board are placed at four years, and the salaries at $4,000 a year each. The bill provides that any person holding a State license would be permitted to apply to this Federal Board and upon payment of a small fee receive a Federal license, and that those persons who do not possess State licenses, upon application to the Federal Board and the presentation of a diploma granting the degree of M.D. from a recognized medical school and the fulfillment of the requirements of the American Medical Association, would receive a Federal license also, the fee in this case being ten dollars. Persons applying for these licenses must, according to the bill, be American citizens and of good moral character. The bill was referred by the House to the Committee on Military Affairs.

Georgia State Medical Board.—Governor Slaton, of Georgia, recently announced his appointments of medical examiners to constitute the State Medical Board under the recent act of the Legislature by which a single board was created on which the three schools of medicine are represented. The five regular physicians on the board were reappointed from the old. The appointments are as follows, all the terms beginning on October 1, 1913: For one year—Dr. J. W. Palmer, of Ailey, Ga., representing the regular school; Dr. C. M. Paine, of Atlanta, Ga., representing the homeopathic school. For two years—Dr. F. M. Ridley, of LaGrange, Ga., representing the regular school; Dr. A. F. White, of Flovilla, Ga., representing the eclectic school; Dr. R. E. Hinman, of Atlanta, Ga., representing the homeopathic school. For terms of three years—Dr. N. Peterson, of Tifton, Ga., representing the regular school; Dr. O. B. Walker, of Bowman, Ga., representing the eclectic school. For terms of four years—Dr. C. T. Nolan, of Marietta, Ga., and Dr. F. D. Patterson, of Cuthbert, Ga., representing the regular school; Dr. A. Fleming, of Waycross, Ga., representing the eclectic school. All terms to date from September 1.

Postgraduate Instruction in the Medical Sciences.—In recent years there has been a growing desire among the physicians and surgeons of New York City for opportunities to keep abreast of the advancing knowledge of the medical sciences, particularly as such information bears upon the problems of clinical medicine. To meet this demand, the directors of some of the leading laboratories in New York have cooperated to offer postgraduate courses in their respective subjects. The institutions cooperating are: The College of Physicians and Surgeons of Columbia University, The New York University and Bellevue Hospital Medical College, The Cornell University Medical College, The Research Laboratory of the New York City Department of Health. Instruction will be by means of lectures, demonstrations, and laboratory work according to the nature of the subject to be presented. For registration and for details regarding the various courses, applicants are requested to communicate with the directors of the respective laboratories. For information as to facilities for studies not specified in the circular, application may be made to Haven Emerson, M.D., 120 East 62d Street, New York.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1914, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in Medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the Secretary of the College, Dr. Thomas R. Neilson, 19 South 22d Street, Philadelphia, U. S. A., on or before May 1, 1914. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

The American College of Surgeons.—On November 13, 1913, will be held in Chicago the first formal meeting for the conferring of fellowships on the members of the American College of Surgeons. Sir Rickman Godlee, the President of the Royal College of Surgeons of England, will deliver the principal address and extend, officially, greetings to the new organization from the Councillors of the Royal College of Surgeons. President J. M. T. Finney will deliver the presidential charge and formally confer the fellowships on all members of the organization who have qualified. Honorary fellowships will be conferred on a small number of foreigners and Americans whom the Board of Regents have selected as worthy of such distinction.

Infant Mortality Low.—The last two weeks in September of this year showed a considerable decrease in the infant mortality in New York City, as compared with last year's figures, and the record so far for 1913 gives the number of deaths among babies under one year of age as 358 less than for the same period of 1912.

New Columbus Hospital.—Plans for the new building for Columbus Hospital, at 226 East 26th Street, New York, have been approved by the State Board of Charities and by the Building Department, and work on it will be begun within a short time. The building will be ten stories high, on a plot 84 x 72 feet, and in the shape of a T. The cost is estimated at $150,000.

Typhoid Fever Among Soldiers.—Ten members of the Newport, R. I., Artillery Company, including the commanding officer, are seriously ill with typhoid fever at the Newport Hospital. It is believed that the men contracted the disease while at Put-In Bay recently on the occasion of the Perry Centennial celebration. Some members of other Rhode Island organizations which were represented at the celebration are also ill with the disease.

Charitable Bequests.—By the will of the late Miss Anna Blanchard, of Philadelphia, the sum of $50,000 is bequeathed to the trustees of the University of Pennsylvania, the net income of which is to be used for the payment or increase of the salaries of professors in the college department, and the sum of $10,000 each to the Academy of the Natural Sciences and the Hospital of the Protestant Episcopal Church.

By the will of the late Reverend William Hutton, of Philadelphia, the sum of $500 is bequeathed to the Presbyterian Hospital and the sum of $2,000 to the Oncologic Hospital.

By the will of the late Sara H. Janvier, of Philadelphia, her entire estate, amounting to $2,600, is bequeathed to the Woman's Hospital of Pennsylvania.

College Vaccinated.—Every member of the faculty and student body of Swarthmore College, Pennsylvania, with the exception of the football squad, was vaccinated on October 4, after the discovery that two of the students at the college were ill with smallpox.

Medical Investigators Indicted.—Five professors in the University of Pennsylvania, Department of Medicine, Philadelphia, were indicted by the Grand Jury on October 3, on twelve bills charging that they did "wantonly and cruelly torture and maim dogs." The indicted men, who were held in six hundred dollars bail each for trial, are: Dr. Alfred N. Richards, professor of pharmacology; Dr. Allen J. Smith, professor of pathology; Dr. Richard Mills Pearce, Professor of research medicine; Dr. Alonzo Englebert Taylor, professor of physiological chemistry; and Dr. Joshua A. Sweet, assistant professor of research medicine. The attorney in charge of the prosecution on behalf of the Women's Society for the Prevention of Cruelty to Animals states that the society is not attacking vivisection, but that it intends if possible to prevent ill-treatment of animals after they have been operated on in medical laboratories. It is the contention of the prosecution that dogs used for vivisection are not properly cared for after the experiments, that they are fed on garbage, and are allowed to lie on cement floors. The trial is likely to excite much interest since upon its outcome will depend very largely the future of Philadelphia as a center of medical research.

Personals.—Dr. Oswald Wayne Smith, superintendent of the St. Louis City Hospital and vice-president of the American Hospital Association, has accepted an appointment as general manager of the Harper Hospital of Detroit, Mich.

Dr. George Whitfield Stephens, for some years assistant medical superintendent of the Arizona State Hospital for the Insane at Phoenix, has been appointed a medical inspector in the United States Army with the rank of first lieutenant and has been assigned to duty in the Philippines.

Dr. Charles W. Stiles of the United States Public Health Service spoke before the Mobile County Medical Society in Mobile, Ala., on September 20.

Dr. Victor V. Anderson of Boston has been appointed to act as psychologist in the probation department of the Boston Municipal Criminal Court. This is the first time that a psychologist has been officially attached to a court of justice. Dr. Anderson has for some years worked with Prof. Munsterberg.

The Late Dr. Van Santvoord.—At a meeting of the Board of Trustees of Bellevue and Allied Hospitals, held September 16, 1913, the following resolutions were adopted: *Whereas*, The Trustees have learned with profound regret of the death of Doctor Richard Van Santvoord, for many years a member of the visiting staff of Harlem Hospital, and *Whereas*, In his death they recognize the loss of one who gave always skilful and faithful service to the hospital and the patients entrusted to his care; be it therefore *Resolved*, That the Trustees spread upon their minutes a record of the esteem in which he was held by them, both as a physician and as a man, as well as a sense of the loss which will be sustained by the hospital from his absence; and be it further *Resolved*, That a copy of these resolutions be forwarded to his bereaved family.

Obituary Notes.—Dr. Edwin Candee Baldwin of Fort Wadsworth, N. Y., State bacteriologist at the Quarantine Station, Rosebank, since 1900, a graduate of the University of Rochester, and, in 1896, of the University and Bellevue Hospital Medical College, New York, and a member of the American Medical Association and the New York State and Richmond County Medical Societies, died at his home on October 3, aged 48 years.

Dr. Fred P. Gale of Plainfield, Vt., a graduate of the University of Vermont, College of Medicine, Burlington, in 1880, died at his home from heart disease on September 21, aged 60 years.

Dr. William Cecil Stafford of Youngstown, O., a graduate of the Detroit Medical College, Detroit, Mich., in 1872, died at his home after a long illness on September 14, aged 66 years.

Dr. James F. Berlet of Philadelphia, Pa., died on September 14 at the age of 62 years. He was graduated from Jefferson Medical College, Philadelphia, in 1877. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. F. Frazer Thomas died at Philadelphia on September 21 as a result of cardiorenal disease at the age of 45 years. He was graduated from the Philadelphia College of Pharmacy in the class of 1890 and from Jefferson Medical College in the class of 1894.

Dr. William H. K. Davis of East Orange, N. J., a graduate of the New York University Medical College in 1886, and a member of the American Medical Association and the New Jersey State and Essex County Medical Societies, died suddenly in his office on September 24, aged 50 years.

Dr. Charles Albert Bemis of West Medway, Mass., a graduate of Jefferson Medical College, Philadelphia, in 1872, died of apoplexy on September 13, at the age of 70 years.

Dr. Arthur S. Koenig of Lewistown, Pa., died at Philadelphia on September 21 from septicemia at the age of 33 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1901 and subsequently served a term as resident physician in the Philadelphia General Hospital. After doing post-graduate work in Philadelphia and abroad he located at his home and became actively engaged in the practice of laryngology, rhinology, and otology. He was a member of the Mifflin County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. Thomas Wistar died of heart disease at Philadelphia on September 27 at the age of 77 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863. He was for many years in charge of the Philadelphia Dispensary, an institution founded by his father, the late Dr. Caspar Wistar. He was for 39 years connected with the Provident Life and Trust Company as medical examiner and director. Also for several years he was connected with Wills Eye Hospital and with the Pennsylvania Hospital. He was a Director of the Wistar Institute of Anatomy of the University of Pennsylvania, an institution established by his brother, the late Dr. Isaac Wistar. He was one of the first in Philadelphia to respond to the appeal for medical aid made at the time of the Battle of Gettysburg.

Dr. Henry Thompson Peirce of New York, a graduate of the College of Physicians and Surgeons, New York, in 1870, and a member of the New York State and County Medical Societies, died at his home on September 27, aged 69 years.

Dr. Sally A. Harris of New York, a graduate of the New York Medical College and Hospital for Women in 1878, died at Scarsdale, N. Y., on September 30, aged 87 years.

Dr. Leonard Ballou Almy of Norwich, Conn., a graduate of the Bellevue Hospital Medical College, New York, in 1876, a member of the American Medical Association, the Connecticut State Medical Society, of which he was a former president, and the Medical Society of New London County, president of the Backus Hospital, Norwich, and during the Spanish-American War, physician in charge of the division hospitals at Camp Alger, Va., and at Camp Wyckoff, Montauk Point, N. Y., died at his home after several months' illness, on September 27, aged 62 years.

Dr. William H. Schenck of Flemington, N. J., a graduate of the New York University Medical College in 1848, died at his home on September 28, aged 87 years.

Dr. Charles Anderson of Santa Barbara, Cal., a retired major of the United States Army, a graduate of the Medical College of Ohio, Cincinnati, in 1874, and a member of the American Medical Association and the California State and Santa Barbara County Medical Societies, was fatally burned in a forest fire on September 17, and died soon after, aged 63 years.

Dr. Alexander M. Todd of Denver, Col., a graduate of the State University of Iowa, College of Medicine, formerly a surgeon in the United States Army, died on September 17, after a long illness.

Dr. John C. Neely of Bainbridge, Ga., a graduate of the Medical College of Augusta, Ga., in 1896, and a member of the Georgia State and Decatur County Medical Societies, died in a private sanatorium at Atlanta, on September 19, aged 43 years.

Dr. Olive Ophelia Nelson of Huntington, Ind., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1900, and a member of the Indiana State and Huntington County Medical Societies, died at her home, after a long illness, on September 25, aged 53 years.

Dr. Emmett Claude Chapman, physician in charge of the Atchison, Topeka, and Santa Fe Railway Hospital, Fort Madison, Ia., since 1894, a graduate of the College of Physicians and Surgeons, Keokuk, in 1878, and a member of the American Medical Association and the Iowa State and Lee County Medical Societies, died at his home, on September 22, aged 65 years.

Dr. Albert Harrison Moore of Ashland, Ky., a graduate of the Jefferson Medical College, Philadelphia, in 1896, a member of the American Medical Association and the Kentucky State and Boyd County Medical Societies, and mayor of Ashland, died suddenly at his home, on September 26, aged 42 years.

Dr. Edwin B. Harvey of Boston, Mass., a graduate of the Harvard Medical School in 1866, a member of the American Medical Association, the Massachusetts State and Suffolk County Medical Societies, and the American Academy of Medicine, for eighteen years secretary of the State Board of Registration in Medicine, president of the State Medical Society from 1898 to 1900, and a counsellor of the society for over thirty years, and formerly a member of the Massachusetts State Legislature, died at his home in Westboro, on September 28, aged 79 years.

Dr. Joseph W. Posthauser of Boston, Mass., a graduate of the New York University Medical College in 1902, died at Burlington, Vt., after a short illness, from septic pleurisy, on September 22, aged 40 years.

Dr. Edward Clefford Town of Narberth, Pa., died on September 29, of chronic nephritis, at the age of 63 years. He was graduated from Jefferson Medical College in the class of 1873. He was Chief Medical Examiner of the Relief Department of the Pennsylvania Railroad, with offices at Broad Street Station, Philadelphia. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a fellow of the American Medical Association.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

B. A. SECTIONS—CONJOINT DISCUSSION ON SYNTHESIS OF ORGANIC MATTER—UNIVERSITY HONORS—NOTES—SANITARY INSPECTORS—OBITUARY.

London, September 19, 1913.

As the proceedings of the British Association are supposed to comprise every department of science the sections are necessarily numerous, but only two or three can claim notice in a medical journal. In most of them the presidents delivered addresses; some on points interesting to experts only, others making a more general appeal or even touching social problems and advocating reforms. Sir R. Temple, in the section of anthropology, urged that a knowledge of the subject should be possessed by those entrusted with administration in all parts of the empire. In physiology, Dr. Hopkins appealed to teachers of chemistry to draw the attention of promising students to biochemistry, so as to increase the number of organic chemists devoting themselves to physiological problems, for although a biochemical society has been lately formed, it is rare to meet a professed biologist sufficiently equipped in organic chemistry to fully understand and discuss the processes of metabolism. In this section a report of the Committee on Anesthetics was presented by Dr. Waller, showing that day after day preventable deaths took place under the administration of these agents by unqualified persons, and proposing a resolution appealing to the council of the association to again represent to the Home Office and the Privy Council the urgent need of legislation to put an end to this abuse. At the Sheffield meeting of the association a resolution was passed to the same effect, and has been since duly pressed on the government. This was two years ago, but nothing has been done, the Cabinet finding no time for the protection of the lives of the people amid its more congenial employment of setting class against class and promoting discontent. Sir F. Hewitt drew attention to three inquests held in the first five months of this year as the result of deaths through the injection of cocaine by unqualified persons and mentioned the many attempts to get legislation by the General Medical Council and other professional bodies, as well as their own association. The government and the public, he said, would not permit porters and cloakroom attendants to drive express trains or work the signals, but were indifferent to the danger of anesthetics being given by unqualified persons. A long discussion followed—if we may so call it, when the speakers taking part in it are practically unanimous. The Dental Association was well represented among the speakers, one of whom mentioned that unqualified dentists numbered 20,000, while the duly qualified were only 5,000. Of course, it is the poorer classes who fall into the hands of the unqualified.

In the section of chemistry, Professor W. P. Wynne appealed for reform in the education of those who followed the science. On two points he was very insistent: (1) Early specialization should be avoided as apt to be disastrous; (2) he would encourage post-graduate training in directions of the student's aptitude or predilection. If the universities would agree on a three years' residence subsequent to the intermediate for an honors degree in chemistry the first reform would be effected. Then for the M. Sc. an approved piece of research occupying not less than a year would be of great service. He who would convert donors and committees to the view that a better return for their endowments would be obtained by post-graduate benefits would do good service to science and the state.

In the section of zoology the president, Dr. H. F. Gadow, said the search for an answer to the question, Why? was the characteristic of our time. The mainspring of science was not utility, nor a desire to do good, but merely "blamed curiosity," the beginnings of which were traceable far back in the lower animals. Comparative anatomy had the casting vote on affinities among resemblances, but that was not all its work. It must reckon with functions—never without them. The animal refused to give up its secrets unless it was regarded as a living individual.

There was a joint meeting of three sections, physiology, zoology and botany, to hear a paper by Professor Benjamin Moore on the "Synthesis of Organic Matter by Inorganic Colloids in the Presence of Sunlight Considered in Relation to the Origin of Life." A good deal of expectation had been aroused as to this part of the program, and a full meeting gathered. Prof. Moore began by remarking that many biologists regarded the problem of life as insoluble and would have it left to psychologists. He had for some time looked at it as an experimental problem and wished to report a step had been taken showing continuity between the organic and inorganic. It was necessary to start far below bacteria which could not survive without nutriment, and so food must have been formed for them even if they had arrived from outside. Such food would have had to be formed by non-living material. He suggested that colloids, as complex chemical molecules became labile, taking up energy from other sources to build up more complex molecules. His experiments showed that colloid iron and colloid uranium, exposed to sunlight or mercury lamp light, led to the formation of formaldehyde, and this he spoke of as the first step from inorganic to organic. Matter, if it could get at energy, tended to take up more and more complex forms. The simplest form of matter was the electron from which came the atom—various atoms being fixed points in the inorganic series. The unstable colloid molecule became labile and took up energy, altering carbon dioxide and water into formaldehyde, the process continuing through greater and greater complexities until it reached the living cell—a new unit that exhibited vital phenomena.

Sir Oliver Lodge opened the discussion and said the synthesis of organic material was not new, it was known in his youth, and now nearly all organic compounds could be synthetized. By supplying energy to a sufficiently unstable molecule you had potentially living matter. But potentially living material was not life—even if life entered into it. If such an experiment could be carried out in a laboratory it would not be the discovery of the origin of life. To speak of it as such was unscientific. It would only be the construction of a physical and chemical vehicle which life could make use of.

Professor Armstrong said the dominant note of the paper was the blessed word "colloid," and like other blessed words "colloid" was used to observe and wrap up ignorance. He disagreed with Professor Moore's statement that a bacterium coming to earth could find no food. He once thought so but

took the opportunity of retracting; instancing the growth of yeast cells, with tartaric acid, sugar, and inorganic material. Formaldehyde in the presence of lime gave sugar, a much simpler way of providing food than Professor Moore's. Vital actions were directed actions as much as a dressmaker's were in building up a dress. Every new growth was formed on an old pattern. We had to account for enzymes and it was no use to bring in colloids at the initial stage.

Dr. Hopkins admitted "colloids" might be one factor, but there was a bad tendency to use them to explain every difficulty. Dr. Leonard Hill agreed with Sir Oliver Lodge, so did Professor Hartog, who mentioned the effect of polarized light on sea water.

The University of Birmingham conferred the honorary degree of LL.D. on five distinguished foreign scientists in commemoration of the visit of the British Association to the city. The recipients were Dr. S. A. Arrhenius, Madame Curie, Dr. Kiebel, Professor Lorentz, and Professor Wood of Baltimore.

The next year's meeting of the British Association is to be held in Australia and Professor Bateson has been elected president. The following year the meeting is to be in Manchester and for 1916 an invitation from Newcastle has been accepted.

On Sunday many sermons were based on the work of the British Association or some special discussion of science in relation to theology. In the cathedral the service was attended by the Lord Mayor in civic state and Sir Oliver Lodge read the lessons, the Bishop preaching the sermon.

During the conference of the sanitary inspectors, the longevity of man having been mentioned, the president, Sir J. Crichton-Browne, told his audience they ought to live 100 years and if they fell short of that they ought to be ashamed of themselves. It would be due to the ignoring of the laws of health by themselves or their progenitors. In another discussion, that on the milk problem, the president interposed in the same positive way with—"As to the milkmaid, why not abolish her and come to electrical milking?" He said he had seen the process in working order and one great advantage was that it was not a typhoid carrier—a most important point, for there were many carriers about that could not be recognized, for they might seem in good health. They must contend against a dangerous notion that had been suggested—that immunization from tuberculosis might result from contaminated milk in infancy.

Dr. Buszard, senior physician to the Northampton Infirmary, with which he was connected for above half a century, died on September 14, aged 74. He qualified in 1860 and afterwards took M.D. Lond. and the Fellowship of the two Royal Colleges. He for many years enjoyed the confidence of practitioners throughout an extensive area around Northampton and was constantly called in consultation. He was many years a magistrate and took an active part in civic and social work—a politician, too, the leader of the Unionists in the county, but respected by all parties as an upright gentleman as much as a learned physician.

Dr. E. J. Nix, physician to All Saints Children's Hospital and St. Elizabeth's Home for Incurables, died on September 11, after a short illness, at the age of 65. He was at one time on the Council of the Medical Society of London and had been President of the Brussels Medical Graduates' Association.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

CESSATION OF THE PLAGUE—GONORRHEAL OPHTHALMIA—PERSONALS.

MANILA, P. I., August 18, 1913.

THE last case of human plague in the Philippine Islands occurred in the City of Manila on May 21, 1913, and the last plague-infected rat was found on June 24, 1913, so that it is now nearly three months since the last case of human plague occurred and two months since the last case of rat plague was detected. The rat catching campaign in the infected district is still being actively carried out; over 5,000 rats per month are being caught in the sections in which plague has heretofore occurred or in places where infection is likely to be found. Twelve sanitary inspectors and 120 laborers are engaged in the work. From the foregoing it would appear that the plague outbreak in the Philippines has been brought to a close and the infection stamped out.

Statements made by a number of hospital physicians indicate that there is reason to believe that there has been a considerable increase in the number of cases of gonorrheal ophthalmia in the City of Manila. This has been attributed to a number of different causes, among the most prominent of which are the rapid spread of public dance halls throughout the city and their increasing patronage by soldiers and by sailors from visiting warships. Recently an ordinance was enacted by the City of Manila which requires all women who dance in dance halls to be provided with a medical certificate issued by a physician of the Bureau of Health which shows that they have undergone a medical examination and have been pronounced to be free from tuberculosis or other dangerous communicable disease. These examinations were begun July 1 and a shocking condition of affairs was revealed. A large percentage of the women were found to be infected with gonorrhea, syphilis, or tuberculosis; and either from reasons of being unable to pass the medical examination or from disinclination to be examined at all, the direct result has been that all dance halls within the City of Manila have been closed because there are not a sufficient number of licensed females to conduct them. But even a greater evil has now come into existence by the opening of dance halls in the suburbs of Manila just over the city line. Steps have already been taken to urge all of the surrounding municipalities of Manila to take similar action, and this is now in a fair way of accomplishment. Cases of gonorrheal ophthalmia were found to prevail quite extensively among young children, and investigation of such cases shows that the infection was in all probability contracted either directly or indirectly from living in the same house with or coming in contact with girls from dance halls. In the campaign against the spread of gonorrheal ophthalmia the public press has been extensively used by the Bureau of Health as an educator. In addition, lantern slides of persons blind from gonorrheal ophthalmia were prepared and a brief description included explaining the manner in which the disease spreads and what measures are to be taken by those who contract it. These have been exhibited during the intermission periods in practically all of the cinematograph theaters in the city.

Colonel Guy Edie, U. S. M. C., who was the first president of the board of health organized by the United States Army in 1898, and who was re-

cently assigned to duty in the Philippines at Zamboanga, has now been transferred, as commanding officer, to the Division Hospital in Manila.

Dr. Louis Schapiro, Chief of the Bontoc Hospital Division of the Bureau of Health, has been suddenly called to his home in Milwaukee on account of illness in his family.

WARNING AGAINST AN APPARENT SWINDLER.

To the Editor of the Medical Record:

Sir:—There co nes to my notice a case of apparent misrepresentation which I deem it best to report to you and if you see fit to give warning to others through the columns of the Medical Record. On August 24 a man came into my office with a very complete line of samples of professional stationery. I gave him a small order which was to be delivered by parcel post by August 30. Inasmuch as it was a small amount and other doctors to whom he had sold had all paid him I did likewise. Needless to say the order has never been delivered; also on writing to the address he was supposed to represent my letter was returned to me marked "Cannot be found." Upon inquiry I find that several other doctors were in the same predicament. The man is of medium height, fairly well dressed, and speaks with a slight German accent. He takes great care in arranging the form of one's order and seems to be all he represents.

W. R. Grunewald, M.D.

8. Nitrogenous Waste Products in the Blood in Nephritis. O. Folin and W. Denis.
9. General Summary of the Significance of Methods of Testing Renal Function. H. A. Christian.

1. **Hospital Administration.**—F. A. Washburn believes that the professional departments of a large modern hospital should each have a single head with an uninterrupted service. Each chief should devote at least a half of each day to his hospital work; his private practice should be secondary. Such men can be obtained only by paying them adequate salaries. The superintendent of the modern hospital should keep in touch with the problems and progress of medicine. There is a tendency in some of the smaller hospitals for members of the staff to attempt surgery for which they have had no adequate training. Too many small hospitals are started without adequate provision for their support.

2. **Atrophic Rhinitis with Ozena.**—F. P. Emerson states that clinically the course of events is as follows: A septal deviation causes a compensatory hypertrophy of the middle turbinal. This is followed by a chronic catarrhal ethmoiditis which interferes with drainage to such an extent that a subsequent active infection results in a sinusitis. The fetor and crusting are probably due to the direct action of a specific pus-producing organism on the tissues, without any preceding true atrophic process. The difficulty in establishing free drainage, where there is an abnormal anatomical development of the bony cells, makes the cure of certain cases of ozena impossible with any intranasal procedure. Whatever aid bacteriology may give us in curing this disease must follow the free drainage of all foci of infection.

3. **Spinal Abscesses.**—J. K. Young notes that psoas abscesses may present themselves at three different periods for the surgeon's consideration, namely, early, intermediate and late. The intermediate period marks the time of surgical inactivity. There is no general rule, however, that can be applied to the abscesses in different regions of the spine. In the cervical region they should be incised early in order to avoid burrowing beneath the deep cervical fascia into the thorax. In the dorsal and lumbar region especially where they are external they should, as a rule, be incised early because of the great pain. In the lumbar region where the abscess has formed a sausage-shaped mass in the iliac region, a delay is sometimes of an advantage as it permits the abscess to elevate the fascia, pushing the peritoneum out of the way and thus avoiding injury to it, and advancing forward toward the inner side of the anterior spine of the ilium, thus avoiding a deep dissection in a region which later might become rapidly infected.

5. **The Classification of Nephritis.**—F. B. Mallory points out that in order to understand the lesions of the kidney it is necessary to separate it into its units and study the effect of injurious agents on each part of the unit. The toxic lesions of the kidney are best classified on an anatomical basis, *i.e.*, according to the part of the renal unit most affected. This classification gives four groups which form the type lesions; they are as follows: tubular nephritis; capsular glomerulonephritis; intracapillary glomerulonephritis; vascular nephritis (arteriosclerosis). Each one of these varieties may occur practically in pure form, but the first three may be, and often are, combined in varying proportions. Whether the first three can be recognized clinically as three distinct types is doubtful. While usually acute, they also occur in subacute and chronic form; vascular nephritis is always chronic.

6. **Urinary Acidity in Nephritis.**—W. W. Palmer reaches the conclusion that mild states of acidosis not infrequently occur in nephritis, and other unsuspected cases, and that the therapeutic use of alkali (in such quantity as to reduce the urinary acidity to that of blood) is often desirable. He also believes that the deviation from the normal of the kidney function in acid excretion is important both in differential diagnosis and prognosis.

7. **The Phenolsulphonephthalein Test.**—E. L. Young discusses the practical value of this test. He finds that it is helpful in cardiorenal cases and serves to place the blame on the organ more at fault. In coma of doubtful origin it casts a strong vote for or against uremia. In acute nephritis it is of less value, as very often a very sick patient eliminates a considerable amount of the drug. In chronic nephritis, inasmuch as a fairly low output is not incomptaible with a considerable length of life if the kidneys can be kept in a state of compensation, some additional fact must be found, which, coupled with this test, will give a more accurate prognosis as regards time. The phenosulphonephthalein test comes nearest to fulfilling all the requirements of a clinically valuable functional test in that it is easy to use, is harmless to the patient, and gives accurate and consistent knowledge of the actual working ability of the kidney, a fact that the practitioner wants more than the knowledge of whether the glomeruli or tubules of the kidneys are affected. In surgery it already has a recognized place.

8. **Nitrogenous Waste Products in the Blood in Nephritis.**—O. Folin and W. Denis conclude on the basis of their study of 50 cases that the accumulation of waste products in the blood varies between figures which are nearly normal to figures which are four or five times as

large as the normal. All the nephritic patients which the authors have examined on high and on low protein diets have shown that on the low nitrogen diets the accumulation of waste products sinks and can be brought down to the normal level. Analytical results have also revealed the fact that the retentions of urea and of uric acid do not go hand in hand. The urea retention is by no means always accompanied by an abnormal uric acid accumulation and considerable uric acid retention may occur without any considerable increase of the urea. These peculiar facts would seem to indicate that in some cases it is more important to exclude meat and other purin food than in others and that a low protein diet does not necessarily imply a meat-free diet. It looks as though by blood analysis it should be possible to determine with a very fair degree of certainty what kind of diet is suitable for each particular case of nephritis. It is already well recognized that the salt content of the food must be regulated in some kinds of nephritis and it seems to us equally clear that similar unequal abilities exist with reference to the nitrogenous products and that in such cases more definite knowledge can be obtained by means of blood analysis than in any other way.

9. Prophylaxis of Insanity. H. C. Podall.
10. Obstetrical Experiences of a Country Doctor. C. L. Sigler.

2. Pulmonary Syphilis.—A. E. Roussel quotes from Fowler's summary on this subject as follows: Cough is one of the earliest and most prominent symptoms at first, being laryngeal, tracheal, or bronchial; later it is due to changes within the lung itself; dyspnea is most marked in the cases which have stenosis of the bronchi; it would seem that in these instances it would be of the inspiratory type; hemoptysis is not common but may occur; expectoration may he profuse, purulent, and offensive but free from tubercle bacilli; pain is not prominent; emaciation is not as extreme as in tuberculosis, but with advanced lesions there is not much difference; night sweats are present in some cases; pyrexia is present when there are extensive lesions; it may be considerable and of the hectic type. Diagnosis, look for lesions of the calvarium, sternum, and ribs. The prognosis is grave, but cases are on record of improvement and cure. Areas of pneumonia consolidation may be overlooked because of the absence of bronchial breathing in cases in which stricture of the bronchi exists; gummata and ulcers in most cases readily respond to antisyphilitic treatment. At the present day one may add to the diagnostic signs the Wassermann reaction, and if possible, the finding of *Treponema pallidum*.

4. Hypertrophic Pulmonary Osteoarthropathy.—H. Brooks believes that a quite sufficient explanation of the lesions of pulmonary osteoarthropathy, and their dependence on pulmonary functional limitation or on such mediastinal growths as impede pulmonary circulation, is furnished by the resultant passive hyperemia which these conditions produce in the distal portions of the body. The lesions are most marked and most likely to appear in those instances where the process begins in early youth, because all tissue hyperplasia is most easily excited during this period. They appear in lesser degree, or not at all, when, as in most cases of pulmonary tuberculosis, the pulmonary and circulatory impediment develops at a period of life when hyperplasia of the periosteum and areolar connective tissue is less readily excited.

8. Treatment of the Cachexia of Malnutrition.—F. Smithies refers to a group of individuals who clinically exhibit weakness, langour, pallor, with or without actual anemia, blotchy muddy skin, anorexia, and dyspepsia, often associated with vomiting and prolonged constipation. In these patients the deviation from the normal can be attributed to no actually demonstrable cause, even after the most careful clinical scrutiny. The cachexia in this type of case is often extreme and may progress to the death of the individual. It is usually ascribed vaguely to "autointoxication," due to constipation, without apparent regard to what may be the initial factor in the production of such constipation. The author reports the case of a female patient aged 26, whose height was 5 feet 1½ inches, and who, fully clothed, weighed 69½ pounds. She had previously had an appendicectomy performed elsewhere, with a second operation for the relief of adhesions, but without relief of constipation, sour dyspepsia, and cramp-like, general abdominal pains. During the year preceding her coming under observation, she had lost in weight more than thirty pounds, was extremely weak, and had gradually become bedridden. The following method of forced feeding was resorted to: A duodenal tube was passed upon the patient in the usual manner. Through it, twice daily, were injected in the early progress of the case 100 c.c. and later, increasing amounts up to 1,500 c.c. of a solution of artificially prepared endproducts of digestion, containing aromatic amino-acids and maltose. No ill effects were observed. The patient was permitted to eat the same sort of diet on which she had been previously subsisting. There were a steady gain in weight and strength, an increased mental activity, a clearing up of the blotchy skin, an improvement in hemoglobin, and an amelioration of the distress associated with constipation. At the end of three months the patient weighed 99½ pounds (a gain of thirty pounds), and was engaged, after nearly two years' idleness, in her trade of hair dressing. At the end of 4½ months she weighed 114½ pounds (a gain of forty-seven pounds) and was well physically. From the results of the author's work he feels warranted in suggesting this therapeutic procedure to others for the treatment of cachexia, where surgical relief is not available; where nonobstructing vomiting has become more or less pernicious; where stricture of the esophagus or cardia prevents ingestion of sufficient food to support life; where functional estimations show low pancreatic activity; where grave anemia exists, and in the asthenia following extensive surgical operations. Split peptonemaltose solutions are well borne in the stomach, and there may exist cases in which their ingestion through the stomach tubes may prove valuable.

1. **Ozone.**—E. O. Jordan and A. J. Carlson conclude that the hygienic value of ozone in room ventilation is hardly worth considering. Human beings are injuriously affected by amounts of ozone far less than are needed to produce even a very slight bactericidal effect. As a deodorizer, ozone in practicable concentrations is a failure. It may mask some odors by its own intensive odor, but this can hardly be considered desirable. The human nose is a better guide for estimating defective ventilation, and ozone does not make pure air any more than strong spices make pure food. In concentrations that can appreciably affect man and animals, ozone is uniformly injurious. The toxic action of strong concentrations has been remarked by all observers.

3. **Diarrhea in Adult Life.**—By R. C. Cabat and H. Emerson. (See MEDICAL RECORD, July 5, 1913, page 42.)

4. **Acute Nephritis and Congenital Heart Disease.**—By H. M. McClanahan. (See MEDICAL RECORD, June 28, 1913, page 1191.)

5. **Etiology of Ileocolitis.**—By C. G. Grulee. (See MEDICAL RECORD, June 28, 1913, page 1188.)

7. **Treatment of Diphtheria Carriers.**—H. Albert during the past few years has obtained good results with the use of a spray of a culture of staphylococci. He has obtained his best results by the treatment of the crypts of the tonsils with a solution of silver nitrate (from 5 to 10 per cent.) applied by means of a thin flexible applicator, combined with a mild alkaline and antiseptic spray for the nasal cavity, and a 1 per cent. solution of hydrogen peroxide as a mouth-wash and gargle.

8. **The Diseases of Porto Rico.**—By E. F. Otis. (See MEDICAL RECORD, July 5, 1913, page 39.)

9. **Colloidal Copper in Cancer.**—R. Weil administered the preparation described by Loeb as colloidal copper in twelve cases of malignant disease, in eight of which the treatment was thoroughly carried out. In most of the cases the treatment resulted in the production of mild constitutional effects, such as fever, chills, nausea, some loss in weight, slight reduction of hemoglobin, and occasional albuminuria or hemoglobinuria. Chemical analysis of two tumors from treated patients failed to reveal the presence of copper, while in a liver obtained at necropsy it was present in appreciable quantity. Judged by certain clinical criteria, which have been adopted as a reliable standard of therapeutic effectiveness, the treatment has not appeared to exert a destructive action on the tumor tissue in any of the cases.

16. **Glaucoma.**—R. Sattler believes that there is a kinship between congenital and senile glaucoma, and that the remote causes of the latter may date back to the pathological conditions in the former. From his experience with glaucoma simplex, surgery is indicated only when an eye still possesses some of its natural compensating properties of the sclera and uveal tunics, but surgery is as successful now for acute inflammatory glaucoma as it has ever been. A pseudoglaucomatous condition should be differentiated from the true type. These conditions have only the cardinal symptoms of high tension in common, and surgical treatment for it alone is not justifiable and miotics have little effect on inevitable conditions in pseudoglaucoma which occurs most frequently as the result of hidden or unsuspected degenerations of the ocular circulatory system, almost always as the expression of pronounced cardiovascular and renal causes. When one can make a positive diagnosis of such cases, one can temporize with anodynes and later, if necessary, perform enucleation.

31. **Myopia.**—S. D. Risley reports his studies on the percentage of myopic eyes, as shown by examinations of school children and others. These studies show that there has been a steady fall in the percentage of myopic eyes in Philadelphia. They also demonstrate the evils of uncorrected errors of refraction. They show that the efforts of the ophthalmic surgeons in the correction of the congenital defects have well-nigh banished from the well-to-do portion of the community malignant myopia and its sequels.

44. **Chronic Laryngitis.**—E. Mayer describes the symptoms and treatment of chronic laryngitis. First among the etiological factors come the obstructive conditions of the nose, causing mouth-breathing and preventing properly warmed air from entering the larynx. Chronic catarrhal conditions of the naso-pharynx may extend to the larynx, but one of the most frequent causes is either the elongated uvula or its papillomatous tip. Hypertrophied lingual tonsils may have to be treated first and follicular pharyngitis and pressure in the auditory canal may cause irritation and trouble. Constitutional, digestive, and cardiac disturbances and the pressure of new growths and enlarged glands may have to be relieved before a cure can be obtained, and dusty occupations or exposure to gases may be a cause. Alcoholics are specially susceptible, as are also males at the age of puberty. Continued use of tobacco often retards a cure. Sudden changes of temperature are very common causes. Improper use of the voice by actors, singers, or public speakers produces some of the most difficult cases to treat. The condition is usually a local hypertrophy, the singer's node occurring at the point between the anterior one-third and the posterior two-thirds of the cord. After removal of the causal factor, the first order must be rest, the more complete the better. Of definite value is the use of sprays and local applications of tincture of the chloride of iron, iodine, alum, etc. Medicated lozenges containing benzoic acid

or krameria during the day are useful. Medicated steam inhalations of compound tincture of benzoin and camphor and iodine, etc., are recommended. The patient should remain indoors fifteen or thirty minutes after each application. Tobacco should be prohibited and faulty methods of speaking corrected. Often a complete change of air and scenery is useful. Cold sponging of the upper part of the body, proper clothing, regularity as to meals and regulation of the bowels are measures recommended.

1. **The Dynamic Side of Biochemistry.**—F. Gowland Hopkins presents an elaborate exposition of the thesis that in the study of the intermediate processes of metabolism one has to deal, not with complex substances which elude ordinary chemical methods, but with simple substances undergoing comprehensible reactions. By simple substances the author means such as are of easily ascertainable structure and of a molecular weight within a range to which the organic chemist is well accustomed. He emphasises the fact that it is not alone with the separation and identification of products from the animal that present studies should deal, but with their reactions in the body, with the dynamic side of biochemical phenomena.

3. **The Detection of Small Amounts of Glucose in Urine.**—S. W. Cole points out the fallacies of Fehling's test and details the advantages of his own method. There are two fundamental principles underlying this method: (1) Charcoal in a certain percentage absorbs the greater part of the non-saccharine reducing substances of normal urine, the greater part of any lactose that may be present, and also a certain amount of the glucose normally present. (2) The filtrate is boiled with sodium carbonate, and thus converted to a reducing substance which reacts with copper when subsequently added. Owing to the great ease with which sugar can be detected in the filtrate after absorption with charcoal, the author had considerable difficulty in finding the exact conditions so that the normal sugar of urine should not give a positive test. He believes that he has succeeded in his object and has also found a simple method for distinguishing lactose from glucose. The details of the method are as follows: In a dry boiling tube or large test-tube place about 1 gram of Merck's pure blood charcoal. Add 10 c.c. of the urine and shake from side to side to mix thoroughly. Heat to boiling point, shaking the whole time. Cool thoroughly under the tap and shake at intervals for about five minutes. Filter through a small paper (9 to 11 centimeters in diameter) into a rather wide test-tube containing about half a gram of anhydrous sodium carbonate. When the fluid has filtered through add 6 drops of pure glycerine, shake and heat to boiling. Note the time when boiling commences. Maintain active boiling for 50 seconds, shaking from side to side to prevent spurting. Immediately add 4 drops of a 5 per cent. solution of crystallized copper sulphate. Shake for a moment to mix the solutions, and allow the tube to stand without further heating for one minute. With normal urine the fluid remains blue, with a variable amount of a greyish precipitate of the earthy phosphates. If glucose is present to the extent of 0.02 per cent. or more above the average normal amount the blue color is discharged, and a yellowish precipitate of cuprous hydroxide forms. The rapidity with which the precipitate forms is a rough measure of the amount of glucose present. With 0.05 per cent. it appears in a few seconds. With 0.02 per cent. it may not appear till 50 seconds. A yellowish precipitate or coloration appearing after 60 seconds must not be taken as evidence of any degree of abnormal glycosuria. It may be due to the normal amount of sugar in urine.

5. **Treatment of Cholecystitis by Cholecystectomy.**—J. O'Conor believes that nothing short of cholecystectomy effects a permanent cure in the great majority of cases commonly known as attacks of gallstones. He has formed a plan of attack which has resulted in rendering removal of the gall-bladder a very simple ten minutes' performance. Making use of the Robson position, and a free vertical semilunar incision, (1) the liver is drawn forward and upward, a superficial incision is made with a knife along the line of attachment (generally adhesion) of the gall-bladder to the under surface of the liver, with the handle of the knife a space is rapidly made for insertion of the left index finger, and in a few moments the gall-bladder is freely detached from its hepatic connection—separation is carried right down to the level of the cystic duct. In order to control oozing a gauze pad is placed in the fossa fellea. (2) Having next carefully isolated the whole operative field, the gall-bladder is aspirated, then seized and incised between two of Lane's forceps, the interior mopped dry, and calculi removed. The gall-bladder is then vertically split down to the level of the cystic duct by a few strokes of the knife, the tip of the left index finger is inserted into the cystic orifice, and the divided gall-bladder, with forceps attached to cut edges, is gathered up firmly, in one grip, in the left hand, and pulled forward. This maneuver renders the operation practically a bloodless one, and greatly facilitates subsequent separation of deep adhesions and examination of ducts. (3) The cystic and common ducts are then carefully palpated with the right hand, and the tip of the left index finger removed from the opening of the former for passage of a small sound. If no calculi are discovered the tip of the finger is replaced, and the assistant applies a strong catgut ligature, just below it, around the cystic duct; this ligature generally occludes the cystic artery. The two flaps of the gall-bladder are then cut away by a few transverse snips of a scissors, about half an inch in front of the ligature. When it is considered expedient to drain the bile-ducts no ligature is applied; the cystic artery and other bleeding points are ligated, and the edges of the cystic duct sutured to the upper angle (peritoneum) of the wound, and a smal drainage-tube fixed in the duct. Before closing the parietal wound by three or four through-and-through strong silk sutures, the author usually inserts a large drainage-tube, which is left *in situ* (fossa fellea) for two or three days.

1. **The Dynamic Side of Biochemistry.**—By F. Gowland Hopkins. (See the *Lancet* abstract.)

2. **Abdominal Surgery.**—W. F. Cholmeley states that the uncertainty of what the surgeon is likely to find is one

of the chief fascinations of abdominal surgery. Experience in this branch demands of the surgeon the following important qualities: the knowledge of when to operate; rapidity of operating; deftness and delicacy of touch; coolness; quick decision; and the knowledge of when to stop and when to continue.

5. **Surgery of Perforated Typhoid Ulcer.**—A. B. Mitchell emphasizes the following points: The modern treatment of typhoid fever in well-equipped hospitals is eminently favorable to surgical success. It is very desirable to operate as rapidly as possible, and to avoid all unnecessary handling and exposure of intestine. These patients are totally unable to bear much manipulation. The quickest way to find the perforation is to go straight for the ileo-cecal valve and trace the ileum upwards. It will rarely be necessary to handle more than 2 to 3 feet of bowel. All sutures should be of catgut, as silk or linen is almost certain to become infected and give rise to a troublesome sinus. The catgut the author uses is prepared by boiling in absolute alcohol for thirty minutes, and stored in 10 per cent. tincture of iodine. These patients bear the Fowler position and continuous rectal saline quite well. Coliuria being a very likely complication, it appears wise to put these patients at once on alkaline treatment.

Renal Function in Mercurial Nephritis.—Ghiron after a practical study of this subject concludes that in the earliest stages of acute mercurial nephritis, with absence of any spontaneous increase of pressure, the kidneys draw a certain advantage from an artificial increase of the latter. This last was worked out by Grocco in 1892 for nephritis in general. More particularly he saw in this law the rationale of cyclic albuminuria which might or might not develop into nephritis. The author hopes to be able to show in time the reason why the increased tension which develops after nephritis may be conservative. In regard to mercurial nephritis the author experimented on rats, and found that at first injections of sublimate were quickly eliminated by the intact kidneys. An hour later, however, the glomeruli and tubes showed structural change. Following up with anilin injections it became apparent that certain zones of the kidney were alone compromised. This distribution appeared to be due to certain methods of accelerating the renal circulation. We obtain the idea that by increasing the tension of the blood traversing the kidney a certain amount of mercury is expelled before it can do harm. No plan of treatment seems to have been evolved to verify this hypothesis.

Apical Disease and Spinal Percussion.—Rüde speaks of this overlooked resource with especial reference to the increasing use of the *x*-ray in this connection. Recently Orszag has studied the value of spinal percussion in the diagnosis of special emphysema. His predecessors in this field were Krönig and von Korányi, and Orszag made use of their results in his work. The author now follows with forty cases of phthisis in which spinal percussion was carefully performed; and in this series there were but three cases of spinal emphysema, the lungs being otherwise free from this affection. This recognition of air content in the apices through spinal percussion does not lead to any practical conclusion and doubtless will not until suitable cases come to autopsy.

Cultivation of the Microorganism of Epidemic Poliomyelitis.—Flexner and Noguchi sum up their long article in part as follows: Cultivation of the central nervous system of men and apes affected with poliomyelitis epidemica (including experimental cases) shows the uniform presence of an extremely minute spherical organism, occurring in pairs, chains or clumps according to the methods of treatment. Various broods show differences in toxicity, and nontoxic broods may give rise to toxic ones. The highly cultivated laboratory germs did not appear to coincide with those already present in the tissues of infected cases, and in some instances could not be made to give rise to the disease. We know that virulent germs cultivated in the laboratory may soon lose their virulence, whereas germs of low toxicity become highly toxic when passed through a succession of animal hosts. It appears well from this study that it is far easier to lay hold of the pathogenic germ of a disease than to make it breed along the wished for lines. The authors will shortly publish the details of the strains of germ bred by them, the modes of cultivation and staining, and the results of animal inoculation.

September 9 and 16, 1913.

Two Years of Experimental Study of Beriberi.—C. Funk, a Fellow of the Beit Memorial Research foundation, began his studies of beriberi at the Lister Institute in 1911; after two years' work his report appears followed by his own conclusions. We are still in complete darkness as to the nature of beriberi. The rice alleged to cause the latter is defective in so-called vitamins and addition of the latter to the diet causes involution of beriberi. However, we are in complete ignorance as to the rationale of this cure. Recovery is so prompt that we naturally think not of a food cure but of an antitoxin which neutralizes a toxin. The neuritis or neurodegeneration of beriberi also suggests the original presence of a toxic substance. But the nerve implication is best regarded as a complication of some primary disease. By eliminating vitamins from the diet of sound subjects a whole train of disease pictures results—scurvy, Barlow's disease, and very likely pellagra, and rachitis. If a subject is deprived continuously of the vitamins he will surely die. These bodies have been recently isolated from nitrogen residues, and we know nothing of the manner in which nitrogen enters into combination. They occur only in the vegetable world, for the animal organism is apparently unable to form substances which are absolutely necessary to its existence.

Contribution to the Causation of Infantile Paralysis.—Bruno insists that when cases of this affection have been recognized one should investigate the household and environment for the presence of domestic and semi-domestic animals. He names especially geese, ducks, and fowl, sheep, cattle, and dogs. The next thing to determine is the state of health of all such animals, and a veterinary should make an expert investigation. The author cites two cases in one family of which the father was a zoöphile who maintained nearly all kinds of domestic animals. The children, aged 2 and 3 years respectively, were attacked simultaneously by a stippling of the tonsils and slight fever, which phenomena were at once followed by disorders of locomotion, which presently assumed the type of infantile paralysis. The ducks appeared to have acted as hosts, and when delivered were ill. One died soon of no discoverable disease. Later three were attacked by a sort of lameness called rheumatism. Hens and geese were not attacked. The three ducks are being studied and their origin traced. Aside from the two cases in the family with acute poliomyelitis the entire family showed a syndrome which while devoid of paralysis exhibited marked involvement of the gastroenteric tract, fever, and in one case severe pains in the back and nuchal region. We naturally look for cases of this origin in rural districts where domestic animals are common; and a colleague of the author has had a similar experience. One child developed poliomyelitis after the death of a steer from a paralytic

affection; there was also a paralyzed fowl among the live stock. The child's father held an official position as tender of live stock in his residential city. Another child treated by the same colleague had associated with a goat recently dead of paralysis.

Diagnosis and Treatment of Syphilis.—No less than four important articles on these subjects are contained in this number. One by Benedek is upon the cutaneous reaction in paralytics with Noguchi's luetin. One series of fifty-two paralytics was tested also with the Wassermann in favor of the last named, as far as end results are concerned. In outspoken tertiary syphilis the luetin reaction is positive in 100 per cent., and always pronounced, while it is much less in evidence in secondary syphilis as well as in parasyphilis. Luetin therefore possesses a special value in tertiary syphilis of the nervous system. Luetin appears from the characteristics of the reaction to behave in a two-fold manner. First it causes an ordinary allergistic reaction, or in other words is an example of anaphylaxis. A wheal is followed by a reddened area and papules develop in the latter. But even in negative cases we may see similar phenomena, in milder degrees, so this reaction cannot be regarded as positive for syphilis unless a certain degree or quality of reaction is present. The second result of a luetin test is the formation of a nodule which presents the histological structure of a gumma or tubercle, and may be spoken of as "provocative" in character. It is proper to regard this sort of lesion as the acme of the various allergic reactions and in no wise a superinfection. Jakob and Weygandt have made a communication on experimental syphilis of the nervous system and find that even in animals the pest can diffuse itself through the body and constitute a generalized infection which special manifestations on the central nervous system, for which the spirochete has a great affinity. The initial manifestation is often a meningitis. Meirowsky continues his studies on living spirochetes and concludes that they proliferate only by budding, the buds breaking off and becoming new units. He therefore believes that we ought to reopen the question, "Is the spirochete an animal or plant?" Finally, Swift and Ellis, of the Rockefeller Institute, New York, conclude their article on the combined local-general treatment of syphilis of the central nervous system. This is best summed up in the case histories appended. A patient with tabes had been receiving intramuscular injections of mercurials without improvement. The authors injected 93 c.c. of normal human serum into the subarachnoid space. This availed nothing, as it was found impossible to clear up the spinal fluid. Nevertheless, the Wassermann reaction showed weakening. Salvarsan was added to some of the injections. In comparatively recent cases both salvarsan and neosalvarsan were injected into the veins and spinal fluid. As patient had shown precocious symptoms of nervous syphilis the permanent recovery in this quarter is looked upon as a successful prophylactic effort.

Abderhalden's Seroreaction in Psychiatry.—Mayer relates numerous experiments made at the Tübingen clinic on patients with dementia precox, progressive paralysis, manic depressive insanity and Korsakoff's psychosis. His conclusions are as follows: The cases investigated and hereby published are not numerous but the observation period has been a long one, and cases of the worst types have been included and frequently tested. Final conclusions cannot yet be drawn. Results are either paradoxic or clean cut. It appears certain that the blood of precox cases contain ferments which invariably antagonize the sexual glands, and also in a majority of cases the cortex and thyroids. In the functional psychoses, on the other hand, there are no such ferments in the blood. The serum of paralytics contains ferments which are defensive against various organs, especially from the cortex. These enzymes do not enter the cerebrospinal fluid. In conclusion we have here a possibly valid method of separating dementia precox from manic depressive insanity and the functional psychoses.

September 4, 1913.

Causes of Pneumonia.—Kruse states that much less time is devoted by the sanitary authorities to pneumonia than to the more infectious diseases, because the latter are regarded as essentially preventable. But pneumonia claims more victims than tuberculosis. Ascher has sought the efficient cause of pneumonia in the "smoke and soot plague" which makes the lungs vulnerable. This view is opposed by facts. Deadly pneumonia is largely a disease of the very young and the old; the four decades between 20-60 showing a lowered incidence and mortality. It is also a disease much more common in the male. The smoke theory, therefore, can throw no light on these groupings. The pneumococcus is not universally regarded as the efficient cause. Many forms of microorganism can cause pneumonia, and if the pneumococcus predominates it may do so because it is a natural denizen of the mouth. If we suppose that man develops pneumonia because of self-infection through activated pneumococci, this is, of course, but a partial explanation. Chill and exposure have always been recognized as leading causal factors. Perhaps equally important are the aspiration of irritant substances and wounds of the thorax. Statistics appear to show that smiths, molders, coachmen, gardeners, and masons—all exposed to cold and sudden changes of temperature—suffer much more frequently from penumonia than those having indoor occupations. When women have outdoor vocations, such as gardening, they seem to be quite as susceptible to the disease as men. All these figures apply to adults during the decades of relatively low incidence. In certain localities in Germany the disease is literally endemic and spares hardly any class. This seems to demonstrate infection as a cause. We know all too little about pneumonia in childhood, but wherever we find the usual infectious diseases of that period markedly in evidence we may count upon finding a high incidence and death rate from pneumonia. Even then it is probable that the number infected falls far short of that which *might* be attacked by carriers of virulent germs.

On the Metamorphosis of Primary Efflorescences.—Herxheimer believes that the organism strives to do away with the acute efflorescence so that if the latter does not vanish it tends to pass into a chronic phase. The papule after its first evolution has always been found by the author to present a lymphocytic infiltration. If an organized virus like the tubercle bacillus penetrates into the skin a proliferation takes place about it. Chemical substances formed during penetration cause the formation of urticarial wheals. The genesis of secondary, chronic papules must be regarded as essentially protective. Practical deductions are afforded by this hypothesis. Thus we have light thrown on Duhring's disease. The multiform lesions may be looked upon as all secondary to some unknown primary manifestation. The author suggests that the latter may be a vesicle. These may be readily infected and form either blebs or pustules. They may run together and form herpes-like areas. The presence of wheals may be due to some toxin formed in the blood by reflex action. Eczema vesicles may become lichenoid papules.

Congenital Lipoma of the Sole of the Foot with Hypertrophy of the Second and Third Toes.—J. G. Saner reports the case of a child, aged 2 years, in whom the condition had been noticed since birth. The tumor appeared to have grown at the same rate as the foot. Operative interference was postponed owing to ill-health. —*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SELF SELECTION (*Continued*).

Self Selection Under Policies for Large Amounts.—The mortality among policyholders who have taken out large amounts of insurance on single applications is too high as a rule, and it is generally recognized that the excessive rate is due chiefly to the presence of adverse selection, especially when the subjects have not previously carried a reasonable amount of insurance.

The following table illustrates the rate of mortality on policies of $20,000 or over, each of which was issued on one application:

Ages at Entry	Insurance Years		
	1–5	6–30	1–30
15–29	145.5	132.4	139.9
30–44	133.2	135.1	134.0
45 and over	109.7	107.9	108.8
Total	120.2	119.0	119.4

This table is based upon data derived from two sources. The number of entrants and the number of actual deaths used in the computation are taken from data collected on lives exposed during the period 1870 to 1900 by the Specialized Investigation of the Actuarial Society of America. In determining the ratio of actual and expected deaths, as exhibited in the table, the M. A. select table of standard lives is employed. The M. A. table was compiled by the combined Medico-Actuarial Investigation Committee which is making an exhaustive study of the vast quantity of material that has been lying practically unused in the files of the various companies.

It is seen in the table that the death rate as a whole is excessive, the total actual deaths in the first to thirtieth year exceeding the normal by 19.4 per cent. Contrary to the belief that has been entertained by many insurance men, the mortality is greater among the young than in the elderly ages, this difference being accounted for, largely, by the deductions of the Medico-Actuarial Investigating Committee which indicate that the expected mortality has been hitherto rated too high among the young and too low in the advanced ages. This difference must be attributed partly, however, to greater care in the medical selection of elderly risks.

A table constructed in the present period should be based upon policies of $50,000 or over, as a $20,000 policy is not considered so large as it was twenty years ago by either the applicant or the companies. Judging from unpublished individual opinions of representatives of the various companies, the ratio of mortality still tends to be unsatisfactory among holders of policies of the larger denominations and a strict medical selection is called for to keep it near the normal.

It cannot be denied that pressure, as well as self selection, is a factor in raising the mortality ratio. It is quite natural that the agency forces should exert every atom of pressure they can summon whenever an application for a large amount of insurance is up for judgment and there is a correspondingly large commission at stake. The exhibition of results showing the mistake of yielding to pressure will undoubtedly have a salutary effect whenever it is needed.

It is unwise for a company to undertake the business of writing large policies unless it can issue enough of them to make up a class which will be sufficiently extensive to support itself and will not have to depend upon the normally low mortality among the holders of small policies to make up deficiencies. The chances for wide fluctuations are too great when dealing with a small experience. The average amount of policies in a large company is in the neighborhood of $2,300, and these form the backbone and strength of the organization.

Nearly every known experience shows that mortality is higher by amounts than lives, which is another way of saying that the mortality on large-sized policies is heavier than on those of moderate size. There is a difference in the relative distribution of numbers and amounts according to age and exposure and part of the favorable mortality for numbers over amounts arise from this difference, not merely because the policy is larger or because there has been selection against the company by the insured or carelessness by the company in selecting risks. There is no question, nevertheless, but what the tendency of men who feel shaky about their hold on life is to over-insure. The mortality shown in the table demonstrates that many applications of a speculative character were approved in spite of the usually careful medical examination and it becomes quite evident that, in addition to the most rigid scrutiny of the physical qualities of such risks, it is highly important to find out if there is a valid reason for acquiring so large an amount of insurance and, furthermore, if the financial condition of the applicant is unimpaired and he is personally able to pay for the insurance. It should always be established that there is a proper relation between the applicant's income and the amount of insurance applied for. A large amount of existing insurance, taken out at intervals during a good many years, is a favorable indication. Suspicion should, however, be aroused when the issuance of a policy for a large sum is soon followed by the application for another. In a very recent and notable case of a speculative character, the individual continued applying for additional insurance as soon as he had the policies previously applied for firmly in his possession until he had nearly a million dollars of insurance in different companies. His death ensued promptly under circumstances which point to premeditated suicide.

Getting After Good Risks.—W. A. Lindly, President American Life Convention, says that agents should be instructed to look after good risks, for there are many written by them that never should have been presented. This makes expense for the company, does no good, and should be controlled in a great measure by the medical directors. Another suggestion is that the medical directors form some sort of a combination by which they can use the same examiners practically in all communities.

Demands on the Insurance Examiner.—A man can be a good practitioner and get along well in his work, but unless he is a student, unless he is a careful examiner of every case brought to him, he will fall down, and this class of men is not wanted as medical examiners.—Dr. Stowell, American Life Convention, February, 1913.

Book Reviews.

Surgery of the Lung. By C. Garrè, Professor of Surgery at the University of Bonn, and H. Quincke, formerly Professor of Medicine at the University of Kiel. Translated from the German by David M. Bancroft, M.D. Second Edition. With one hundred and fourteen colored and other illustrations, and two colored plates. Price $4.00. New York: William Wood & Company, 1913.

Since the publication of the first edition in 1903 the surgery of the lung has made considerable progress, necessitating altering and re-writing to a very great extent, and the addition of many illustrations. An anatomically trained eye in surgery of the lung is absolutely necessary and the anatomical topographical introduction will not be unwelcome to the surgeon. Chapter II deals with the pathology of the pneumothorax and Chapter III with the methods of maintaining a difference of pressure which has enlarged the sphere of surgical operation to an extent hitherto unimagined. For sixteen years surgeons have sought for means to prevent the collapse of the lung when the thorax was opened and a history of this work is given. Descriptions and pictures are given of Sauerbruch's cabinet, the universal differential cabinet of Willy Meyer, Engelken's apparatus for increasing the pressure, Tiegel's simplified mask apparatus, Schoemaker's apparatus, Dräger's combined apparatus, Lotsch's apparatus, the simple apparatus for increasing pressure by mens of hydraulic bellows, constructed by Steinmann, Elsberg's apparatus for intratracheal insufflation, etc. The following chapters deal with general surgical technique, injuries of the lung, pulmonary suppurations, tuberculosis of the lung, actinomycosis of the lung, pulmonary fistulas, Trendelenburg's operation for embolism of the pulmonary arteries, tumors of the mediastinum, the pleura and the lung, pulmonary echinococcus, foreign bodies in the lung and bronchi, hernia of the lung and pulmonary emphysema, the surgical treatment of rigidity of the thorax. The book is a handsome one, the text is clear, the pictures admirable, and the getting up of this work reflects great credit upon the publishers.

Medical Union Number Six. By William Harvey King. Price Fifty Cents. Philadelphia: Boericke & Tafel, 1913.

This novelette is the story of a physician who is shipwrecked on a desert island and is cut off from civilization for thirty years. He returns to New York to find the medical and clerical professions under the domination of a medical union which makes a fetish of union principles, beside which all claims to human sympathy or service fall into insignificance. The people finally rebel against the outrages of organized medicine, and the medical union retaliates by turning loose in the nation 2,000,000,000 rats infected with bubonic plague and, as a result, 60,000 human beings die, but the power of the union remains unbroken. The story is simply the vehicle for demonstrating that any attempt to apply the principles of the labor union to the profession must result in commercializing the profession and degrading professional ideals, paralyzing individual effort and destroying the scientific spirit.

Medical and Surgical Report of the Presbyterian Hospital in the City of New York. Vol. IX, July, 1912. Edited by John S. Thacher, M.D., and George Woolsey, M.D. New York: Corlies, Macy & Company, Inc., Printers, 1913.

Some doubts may be raised as to the real utility, commensurate with the expense of publication, of the annual medical and surgical reports of hospitals. The articles contained in these reports, in most instances, have already appeared in the various periodical journals. These doubts will be dissipated if one glances over the pages of the present volume, which, in the beauty of its typography and illustration, and in the fine quality of its paper, justifies, from the esthetic viewpoint alone, the gathering together in a single volume of the scientific contributions of those connected with one institution. But there are other reasons why such work should be preserved in this form. The sense of loyalty to the institution, the *esprit de corps* of its members, the stimulating influence on the younger men, and the demonstration to the world at large of the vast amount of scientific work that may be carried out in a single institution—all these more than justify the publication of such reports. The following are a few of the articles in this volume: Visceral sarcomata, by W. Gilman Thompson; transfusion of blood in pernicious anemia, by David Bovaird; the Cammidge reaction in diseases of the pancreas, by the late Francis P. Kinnicutt; and purpura, by John S. Thacher—all of which are reprinted from the Medical Record; the electrocardiogram in clinical medicine, by Walter B. James and H. B. Williams; acute pericarditis in children; the absorption of food in typhoid fever, by Eugene F. Dubois; the operative treatment of fractures, by Joseph A. Blake; the clinical features and treatment of acute gastric and duodenal ulcer, by Ellsworth Eliot, Jr., J. A. Corscaden, and J. W. Jameson; postoperative intestinal obstruction, by George Woolsey; intestinal diverticula, by John A. Hartwell and Russell L. Cecil; operations upon the appendix, by Clarence A. McWilliams; and the surgical treatment of spinal cord tumors. The editors are to be complimented upon the splendid manner in which they have acquitted their task.

Transactions of the American Pediatric Society. Twenty-fourth Session, held at Hot Springs, Va., May 29, 30, and 31, 1912. Edited by Linnaeus Edford La Fétra, M.D. Vol. XXIV. Chicago: American Medical Association Press, 1913.

The yearly volume of transactions of the American Pediatric Society is awaited by the student of pediatrics as a valuable addition to his special library, for he is sure to find in it a mirror of the latest advances and trend in the study of children's diseases. The present volume amply fulfils this expectation. The opening address by W. L. Carr discusses the relation of the American Pediatric Society to the reduction of mortality in infancy and childhood. In the domain of infant feeding there is an article on the dextrins and maltose by Southworth, one on maltose by Morse, one on the effect of heated and superheated milk on nutrition by Coit, one on the method of studying and teaching the principles of infant feeding, with special reference to the importance of the energy line, and one on the problems of infant feeding by Eaton. The articles pertaining to infectious diseases are as follows: Epidemic sore throat, by Ruhräh; inclusion bodies in scarlet fever, by Nicoll; typhoid fever in infancy, by Griffith; serum treatment of pneumonia, by Freeman; the Wassermann reaction in children, by Churchill; the use of salvarsan in children, by Le Fétra, and the mode of infection in cerebrospinal meningitis, by Bovaird. Other articles are the following: Coagulation time by Carpenter and Gittings; congenital obstruction of the posterior urethra, by Knox and Sprunt; metabolism in amaurotic family idiocy, by Crohn; infant metabolism, by Benedict and Talbot; delayed development treated by thymus gland, by Kerley and Beebe; diabetes mellitus in an infant, by Eaton; chondrodystrophy, by La Fétra; the pyloric reflex in pyloric stenosis, by Cowie; acute yellow atrophy of the liver, by Huber; infantile scurvy and modern conditions, by Northrup, and milk commission standards, by Coit. The volume is handsomely illustrated.

Pathological Inebriety: Its Causation and Treatment. By J. W. Astley Cooper, Medical Superintendent and Licensee of Ghyllwood Sanatorium, near Cockermouth, Cumberland. With introduction by Sir David Ferrier, M.D., F.R.S. Price, $1.50 net. New York: Paul B. Hoeber, 1913.

In this small volume the subject of inebriety is considered in a very rational manner. After presenting his classification of the different types of inebriety, the author discusses its etiology, emphasizing the fact that defectives are liable to become inebriates and that inebriates are very apt to produce defectives, thus developing a vicious circle, the importance of whose recognition is very great. In the section on treatment he divides it into treatment by isolation, treatment by specific drugs, and treatment by suggestion, and insists that the inebriate must receive the benefit of all three if his "cure" is to be permanent. He agrees with other writers that the inebriate must remain a total abstainer or else he is practically certain to relapse. In view of the present unsatisfactory treatment of inebriates in this country the book is timely and its lesson is one that could be learned with profit by our authorities.

Grundriss der psychiatrischen Diagnostik. Nebst einem Anhang enthaltend die für den Psychiater wichtigsten Gesetzesbestimmungen und eine Uebersicht der Gebräuchlichsten Schlafmittel. Von Prof. Dr. Julius Raecke, in Frankfurt a. M. Mit 14 Textfiguren. Vierte vermehrte und verbesserte Auflage. Preis, 3 marks. Berlin: August Hirschwald, 1913.

The present, the fourth, edition of this excellent little book has followed the previous one within a matter of months. It is slightly enlarged, and improved, and brought up to date. It even mentions, for example, the finding of spirochetes in the brain in general paresis, and the more important newest hypnotics. The plan and classification remain the same.

The Tonsil and the Voice in Science, Surgery, Speech, and Song. A Comprehensive Monograph on the Structure, Derangements, and Treatment of the Tonsils, and of the Relation to Perfect Tone Production. A Research Study with Original Contributions from the Highest Medical and Voice Authorities. By Richard B. Faulkner, M.D. (Columbia University). With an Introduction by Prof. George M. Sleeth, Instructor in Elocution, Western Theological Seminary. Ten Illustrations. Pittsburgh, Pa.: The Presbyterian Book Store, 1913.

The object of this book is to present known facts, the latest views of the most eminent authorities, and the indications which denote safe lines of treatment as against the apparent indiscriminate and reckless disregard of tonsillar function. Six medical and six voice questions are answered by renowned artists, and teachers, and scientific investigators. These questions are: Have the normal faucial tonsils any function? (Addenda from original sources and addenda showing wide diversity of views are presented.) What are they? What effects are directly due to their removal? Have phonetic changes been noted? Would you advise the removal of normal tonsils? Remarks. Are the normal faucial tonsils of any use to singers? How, or in what manner, are they of use to singers? Do you know of any instances in which the voice was impaired or ruined after their removal? Is removal of tonsils advisable in singers? Remarks. In concluding his work Dr. Faulkner adds a few "don't forgets," of which the following is an instance: Don't forget that the tonsil is a natural organ; that you have no right to destroy a natural organ; that the physiologico-biological values of the tonsils have not been proved; that by enucleation you destroy values of which you have no knowledge; that the tonsil has important mechanical functions, a buffer, a cushion, a fulcrum, a compensator; don't forget that Young found all *prime donne* with extraordinary voices had big tonsils; don't forget that among 8,000 pupils examined by Neustaedter, tonsils are largest in the best pupils, and that the best singers have 50 per cent. more tonsils than the poorest. Professors in Columbia University, Harvard, Pennsylvania, Johns Hopkins, McGill, and other universities, from whom he received responses, evidently do not grant *carte blanche* permission to their students for the promiscuous performance of tonsillectomy. The author strikes a timely note of conservatism, which it is to be hoped will reach the ears of the many who are given to operate on every slight pretext.

The People's Money. A Brief Analysis of the Present Position in America, with Some Observations on the World-Organization of Labor. By John W. de Kay. Price, one shilling. London: Effingham Wilson, 1913.

The author opens his tractate with a scathing indictment of the hitherto unbridled money power in the United States. He indicates the broad lines along which this power may be effectively controlled in such a manner as to avoid unjust interference with capital or unreasonable restrictions of individual endeavor. He advocates federal control of corporations and a central bank. Himself a "captain of industry," he shows a broad humanitarian spirit in dealing with the problems of labor and advocates not only a nation-wide, but a world-wide, organization of labor as offering the only well-founded hope of securing justice from capital.

Therapeutics of the Gastrointestinal Tract. By Dr. Carl Wegele. Adapted and Edited, with additions on the Diagnosis of the Diseases of the Esophagus; Diagnosis of the Diseases of the Gastrointestinal Tract; Duodenal Tube and Its Uses; Diseases of the Pancreas, and *X*-ray Examinations of the Gastrointestinal Tract. By Maurice H. Gross, M.D., Attending Gastroenterologist to the Har Moriah Hospital, and I. W. Held, M.D., Attending Physician to the Har Moriah Hospital. With 52 illustrations in the text and two figures in colors on one plate. New York: Rebman Company, 1913.

This book is a specially conscientious and thorough treatise upon the therapy of stomach and intestinal diseases, and comprises, in short systematic arrangement, many important facts which are scattered in specialized works too exhaustive for the busy practitioner; it lays main stress upon and consistently carries out the dietetic, physical, and hygienic treatment of gastrointestinal diseases. Extensive additions have been made to the German work, such as a separate chapter on the esophagus, and one on the *x*-ray diagnosis of stomach and intestinal diseases. There has also been added a chapter upon the comparatively new subject of the "Duodenal Tube." There is an important chapter on the diagnosis and treatment of diseases of the pancreas, beside minor chapters such as parasitic diseases and diseases of the intestinal blood vessels. It is hoped that the more complete form of book will be found useful to those engaged in general practice.

Müller's Serodiagnostic Methods. Authorized translation from the third German edition. By Ross C. Whitman, B.A., M.D., Professor of Pathology, University of Colorado, School of Medicine. Price, $1.50. Philadelphia and London: J. B. Lippincott Company, 1913.

This is a collection of all the more important methods of serum diagnosis now in use. The description of the various methods has been made exceedingly exact and a complete and detailed list of reagents and apparatus is given for each test. Theoretical considerations have been omitted entirely since many of the methods are so new that their value is yet unknown. The book will save many weary hours in the library and will prove a valuable addition to the library of any laboratory in which serum diagnosis is attempted.

Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and subjects. Second Series. Vol. XVII. Washington, 1912.

This volume contains titles from Suaheli to Testut, to the number of 5,928 author and subject titles of books and pamphlets and 36,898 titles of articles in periodicals. Of particular interest is the catalogue of tests illustrating the history of medicine in a library of the Surgeon-General's Office, which fills 90 pages of this volume.

Treatment of Tuberculosis. Ordinary Therapeutics of Medical Men. By Prof. Albert Robin, of the Faculty of Medicine of Paris. Translated by Dr. Leon Blanc, of Aix-les-Bains, assisted by Dr. H. de Meric, of London. Price, $7.00 net. London: J. & A. Churchill. Philadelphia: P. Blakiston's Son & Co., 1913.

This English edition of Professor Robin's book is dedicated by the translator, Dr. Blanc, to the late John Pierpont Morgan, the great American financier and philanthropist, in token of gratitude for the creation of a tuberculosis annex in connection with the hospital at Aix-les-Bains, which is likewise a gift from Mr. Morgan. Aside of the sentiment expressed in the dedication, by reason of which this book should be of interest to the profession as well as to the laity of the United States, the work gives a thorough survey of the medical aspect of tuberculosis, consecrates an excellent chapter to the social defense against this disease of the masses, and merits careful study by all interested in the tuberculosis problem. This chapter referred to is intended to inspire the non-medical world with the desire to do its duty in the fight against tuberculosis, either by philanthropic gifts or personal service. In the chapters devoted to the treatment of tuberculosis *per se* one finds an excellent review of what is known up to date concerning predisposition. To the enthusiast of specific treatment by culture products, the statement that "the discovery of the bacillus has not as yet ameliorated the treatment of pulmonary phthisis" must seem discouraging. Professor Robin does not, however, entirely disapprove of tuberculin therapy. In his own practice he uses only the freshly prepared solutions of the purified tuberculin made by the Paris Pasteur Institute. He cautions practitioners to use tuberculin only in such patients whose organism is still resistant and capable of an effort toward reaction in pulmonary foci. In all other cases he urges the "hygieno-dietetic medication for the repair of waste, remineralization, and direct antisepsis." Under remineralization he emphasizes the treatment of acid dyspepsia or gastric stasis, the giving of food containing but very little acid, and the administration of lime and magnesia. As valuable medicinal agents to counteract demineralization he recommends cod liver oil (providing it is well digested) and the various arsenical preparations (cacodylate of sodium and arrhenal). Among the local medications highly endorsed by Professor Robin we must mention the method of revulsion, which the translator might have done well to call counterirritation. This local therapy has been virtually abandoned in modern phthisiotherapy, yet the reviewer agrees with the distinguished author that counterirritants are of inestimable value in not a few cases of pulmonary tuberculosis to relieve pain and congestion. The book abounds in numerous valuable prescriptions for the symptomatic treatment of pulmonary tuberculosis and the extra pulmonary tuberculous affections. Hydrotherapeutics and climatotherapy receive due mention. In short, this volume of 600 pages contains much of interest to the phthisiotherapeutist, the patient, and all others interested in tuberculosis. Aside from rather numerous typographical errors, for which perhaps the proofreader alone is responsible, only praise can be bestowed upon author and translators for having given to the profession so valuable a treatise on an important subject.

Society Reports.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Twenty-third Annual Meeting, held in New York City, September 2, 3, and 4, 1913.

THE PRESIDENT, DR. F. HOWARD HUMPHRIS OF LONDON, ENGLAND, IN THE CHAIR.

President's Address.—Dr. HUMPHRIS discussed the relation of electrotherapeutists to each other, to their professional colleagues and to the public at large. He urged careful study and modesty, and the recognition of the fact that electrotherapy was but a segment in the great chain of scientific discoveries. Electrotherapeutists should not trespass outside the bounds of their own specialty. Their duty to the public at large could be summed up in the one great word "honesty."

Report of Committee on Induced Current, Including Alternating and High-Frequency Currents and Apparatus.—Dr. FREDERIC DE KRAFT of New York said that so much mystery seemed to be attached in the minds of many as to the action of high frequency currents, and more especially to the heat effects attending their passage through the body, that it seemed not inopportune to inquire into the matter somewhat in detail. It had long been an established fact that every electric current warmed the conductor through which it passed. The resistance which the current encountered in its passage through a conducting medium was to a large extent responsible for the conversion of a part of the electrical energy into warmth. Last year he had spoken of a new series multiple spark gap. The sparks in this were discharged unmuffled in the open air. With this method the silver points were rapidly oxidized. After many experiments, he had induced the manufacturer to exclude the air, and in the new series multiple spark gap the sparks occurred practically in a vacuum. Low frequency alternating currents had electrolytic properties. With currents of very high frequency no electrolytic effect was noticeable. The warming effect ofauto-condensation was different from that obtained by any other artificial method. It occurred from within, in the interior of the body, in which every single cell participated. As a result of the heating of the blood and muscles the entire heat regulating apparatus of the body was exercised, probably brought about by a direct stimulation of the sympathetic nervous system. The blood rushed to the surface of the body and venous congestion was relieved. Anemia of the splanchnic area ensued. Visceral congestion was relieved. After this subsided the blood stream returned again to normal channels, and diseased organs and areas received a fresh supply of oxygenated blood.

Phototherapy and Apparatus.—Dr. HERBERT F. PITCHER of Haverhill, Mass., said there had been nothing new in the way of apparatus reported during the past year. Heliotherapy had received some attention in the manner of treating laryngeal tuberculosis and tuberculous glands. The red light had been used in the treatment of pleural effusions. Of the many methods used in the treatment of alopecia the ultra-violet light was one of the most cleanly and convenient. Fluorescence in the tissues was a question which had not been satisfactorily solved, and he suggested the systematic trial of the method in the treatment of diseases amenable to all forms of light.

Static Currents and Apparatus.—Dr. FRED H. MORSE of Boston said that much more work was being done with the static current than for several years past. The improvement in apparatus and some new modifications of the older methods of application came in the line of marked advancement. For instance, the multiple spark gap advanced by Dr. Bishop, the pencil brush discharge electrode for producing a violet spray from the positive side of the machine, without a possible chance of getting the hitherto unpleasant spark, advanced by Dr. de Kraft, and the increased efficiency of the positive brush discharge, where a many pointed metal electrode is attached to the positive side of the machine, the patient holding the negative electrode, a powerful anode spray being produced which is applicable in the treatment of joint affections, inflammations of the middle ear, and in various cutaneous diseases, the efficiency being greatly increased by interposing a multiple spark gap in the circuit on the positive side.

Roentgenology.—Dr. G. E. PFAHLER of Philadelphia reviewed the advances made during the past year in Roentgenotherapy and *x*-ray diagnosis.

Mechanical Vibration Therapy, Exercise Therapy and Apparatus.—Dr. MARY ARNOLD SNOW of New York said the therapeutic application of mechanical vibration had been greatly broadened during the past year by its use in cases of high blood pressure and in the treatment of splanchnic neurasthenia.

A Plea for the Scientific Teaching of Electrotherapeutics.—Dr. WILLIAM BENHAM SNOW of New York read this paper. There were three distinctive features of electricity characteristic of its employment in art, commerce, and medicine—(1) electrolytic, (2) thermic, which included light production, (3) mechanical. Employed with a distinctive recognition of these peculiar effects, the currents best adapted for each were respectively: the constant current for the electrolytic effects, the static currents for the mechanical effects, and the high frequency currents of d'Arsonval and Tesla for the thermic effects. The constant current could be employed for other effects, but it was essentially the current employed for the removal or destruction of redundant or neoplastic growths by the method of Gautier, Massey, and others. The static current possessed peculiar qualities capable of producing tissue drainage, removing the infiltration from swollen glands, joints, and other structures as no other measure would. The action by which this was accomplished was purely mechanical and largely due to its high voltage and diffusion, and to its peculiarly energetic effect in producing tissue contraction; when, by the induction of intrinsic activity in the structures of a part, the products of inflammation or defective metabolism were expelled and circulation reestablished. The high frequency current produced the thermic effects by heating the tissues, and particularly so when passed between electrodes placed at opposite sides of the body or part. This was accomplished without the production of any electrolytic action whatever, and might be regulated to the tolerance of the patient and employed with practical safety for the induction of local hyperemia and restoration of local metabolism in the field through which it passed. Several currents, as the sinusoidal, induced and constant currents, produced mechanical effects which were valuable in selected cases by special technique. The constant current was the only current capable of causing electrolysis. While other currents produced heat, the high frequency current was the choice in all cases for the production of thermic effects with hyperemia. From this point of view the choice of electrical methods to meet definite therapeutic indications was placed upon a scientific basis, which was demonstrable and readily understood by the beginner. No one should presume to use electricity as a therapeutic agent without understanding the methods and indications for its employment—how, when, and why to use it. Otherwise success was impossible, because the element of dosage, which included time, current strength, and method of employment, was vitally important.

Emphysema: Allied Conditions and Their Treatment.—Dr. ERNEST KINGSCOTE of London, England, read this paper. He said that increase of the chest excursion and reduction of the hyperresonance in emphysema were obtained by a new method of exercise consisting of first binding a large towel tightly around the lower ribs during forced expiration, then taking three very slow forced inspirations in succession, breathing through the nose. The maneuver was repeated three times a day for three months. Improvement was noticeable in a week. Between the emphysematous cavities were millions of disused air cells with all their elastic tissue intact. By means of these exercises the disused air vesicles were once more brought into action and as they expanded they gradually squeezed up the emphysematous cavities and the patient became once more endowed with movable elastic lungs. This opened the door to the treatment of a number of otherwise intractable conditions, such as asthma, angina pectoris, diabetes, tuberculosis, chronic dyspepsia, myxedema and the goiters, all of which were characterized by stasis of blood in the brain and abdominal organs. The brain and the abdomen depended largely on the expansion of the upper thorax for getting rid of their venous blood. Therefore the increase in the chest excursion by the method described was of vital service combined with other methods. Improvement was noticeable within a week.

Appendicitis: Its Treatment and Prevention.—Dr. S. ST. JOHN WRIGHT of Akron, Ohio, presented this communication. The anatomical similarity of the appendix and the colon with its circular and longitudinal muscles led the writer to believe that the appendix might be kept in a normal condition by the frequent use of the slow sinusoidal current. The necessary apparatus cost less than an appendectomy, could be made fool-proof, and might safely be used by almost anyone. The daily use

of this current was recommended instead of the incessant use of laxatives, and it was considered best to have the patient install the apparatus in the home and use it regularly.

Ionic Medication: a Neglected Treatment in America.—Dr. F. B. Granger of Boston, Mass., in this paper outlined basic rules for the correct polarity and choice of drugs in ionic medication, giving the best percentage strength of solutions and of current strength. The results of experiments and of clinical work were given in detail.

The Continuous Current and Some of Its Advantages as a Therapeutic Agent.—Dr. Francis B. Bishop of Washington, D. C., read this paper. When applied to nerve centers or nerve tracts the functions of distant organs were readily influenced by the constant current. All physiological functions of the body were associated with definite body electrical currents and those currents were absolutely necessary to the proper action of all such functions. In disease the body currents of the affected part became weaker. Any form of stimulation applied to a muscle or nerve or to the surface of the body produced body currents proportional to the degree of stimulation and to the physiological activity of the tissues. The effect of treatment by any physical agent depended upon its power to stimulate the activity of these body currents. The constant current had *par excellence* the power to supplement the action of the normal body currents. Numerous diseased conditions were cited wherein its use was particularly recommended.

Osteosarcoma of the Inferior Maxilla; a Clinical Report.—Dr. F. C. Tice of Roanoke, Va., reported a case diagnosed clinically as osteosarcoma of the inferior maxilla successfully treated by the *x*-ray.

A Plea for the More Extensive Use of the Sinusoidal Current.—Dr. Fred H. Morse of Boston read this paper. In the treatment of certain pathological conditions results obtainable by the sinusoidal current differed considerably from what was to be obtained by the static, galvanic, faradic, or high frequency currents, or any of their modifications or combinations. Owing to the character of the current, it was possible to use a considerable amount of current and produce vigorous muscular contractions on both voluntary and involuntary muscles without the usual painful effects that would result from the galvanic, faradic, static, or induced currents. It was very useful in the treatment of dilated stomach, with or without gastroptosis. In any place where the faradic or static currents were indicated and could not be tolerated, we had in the sinusoidal current an agent of greater value than was generally understood or appreciated by the great majority of physicians.

Deforming Arthritis and Intestinal Stasis.—Dr. A. B. Hirsh of Philadelphia, said that physicians trained in physical treatment methods had with such full satisfaction relieved or cured chronic arthritis with enteric torpor, that it came rather as a surprise to learn that the intimate etiological relation thought to exist between the two symptom groups was now being denied by some authorities. Their position seemed to rest on laboratory studies rather than on clinical results. Until more dependable tests were found, the conflicting views of authorities as to the diagnosis of urinary extractives in arthritis must make the physical therapist continue to depend on the presence of indicanuria and on the fractional proportion between the conjugate and preformed sulphates as guides to intestinal proteid putrefaction, both as the cause of the joint trouble and as indications for its treatment. Other sources of infection should not be overlooked. The treatment included regulation of the bowels, a suitable dietary, exercises and hygiene, artificial support of ptosed abdominal organs, and the application of the static sparks to the joints for the removal of abnormal deposits and to the muscles for the relief of spasm.

Some Ideas Fertaining to Electrotherapeutics.—Dr. Anthony Bassler of New York said he seriously questioned the advisability of a great quantity of the literature that had been advanced in connection with electrotherapeutics, because some of it had hampered the progress of the specialty in the estimation of the best men in medicine. Numerous articles had appeared in which a large series of a certain line of cases were mentioned where the diagnosis was stated without as much as a qualifying symptom justifying the diagnosis. How could we ever hope to arrive at a definite opinion of the value of any measure of therapeutics unless the very closest minutia had been employed in the diagnosis, and all of the methods of treatment described. Instead of adopting the enthusiastic standard, the standard of work, experience and personal questioning should be installed, and such statements as might be made should always be accompanied with the reasons for the diagnosis and matters pertaining to the treatment.

Curability of Certain So-Called Incurable Chronic Diseases by Modern Methods.—Dr. Byron S. Price of New York said that chronic noninfectious disease conditions had long filled a conspicuous place in the list of "incurable diseases." In these conditions oxidation was always below par, stasis existed, and hyperemia, if present, was of the venous or congestive type. The result tended to one of scar tissue production, as in spinal-cord lesions, arteriosclerosis, chronic interstitial nephritis, chronic neuritis, etc. This class of cases required some means of direct tissue-cell stimulation for the production of oxidation and elimination of waste. These diseases had been left without hope of cure until William J. Morton conceived and made possible the application of the high frequency currents in their treatment. The indications were to end or modify the toxin production, and to eliminate as rapidly as consistent the waste products already retained in the tissues.

The Use of the Series Spark-Gap on the Static Machine in Roentgen Therapy.—Dr. George E. Pfahler of Philadelphia described an addition to the muffler of the static machine which introduced a series spark gap on either the positive or negative side of the circuit. It answered the requirements of being able to adapt the spark when the machine changed its polarity; it was noiseless; it could be adjusted from an adjoining room; and it did not furnish a path for leakage of current.

Food as a Factor in the Causation and Cure of Disease.—Dr. J. W. Torbott of Marlin, Texas, read this paper. The balanced ration from the true standpoint of caloric needs of the body was not commonly followed by either doctor or patient. The high protein diet so largely used now formed more toxic products, overworked the thyroid, liver, and kidneys more than any other diet, and thereby invited infections and the sequelæ following infections in the form of arthritis, nephritis, arteriosclerosis, neurasthenia, neuritis, and many other chronic diseases. One of the greatest factors then in the cure and prevention of such diseases was the adoption of a balanced ration of clean, well-prepared, nutritious, low protein food, laxative enough in character because of the cellulose and fruits to maintain intestinal drainage without irritation and give at the same time proper nutrition. The doctor should be the leader of this movement in educating the people through his patients by precept and example as to the great importance of dietetics from the standpoints of economics, as well as the cure and prevention of disease, to the end that they may know how to maintain health on a balanced, varied ration for the least amount of money.

The Indications and Contraindications of Electrotherapy in Gynecology.—Dr. H. F. Pitcher of Haverhill, Mass., said that after treating diseases of the pelvic organs for over thirty years he had yet failed to find a remedy which would replace electrotherapy in many of the diseases of women. Pelvic diseases in which he had found electrotherapy as the remedy of choice were gonorrhea, dysmenorrhea, menorrhagia, ovarian congestion and inflammation, chronic catarrhal and exfoliative endometritis, endocervicitis, chronic metritis, subinvolution, and the absorption of adhesions and exudates as the results of old inflammatory troubles.

Electrical Massage.—Dr. C. O. Files of Portland, Me., read this paper. By electrical massage by means of the hand of the operator the value of the massage was vastly intensified and the field of its use greatly broadened. In the anemic condition introducing many wasting diseases this modality had proved its efficacy. Static electricity had ben useful in this class of cases, but electrical massage had secured speedier and more brilliant results. There was no form of electricity that could be compared with electrical massage in hastening circulation and giving strength to muscles.

The Storage Element in the Therapeutics of the Constant Current.—Dr. Alfred T. Livingston of Jamestown, N. Y., related the case of a man on whom he had applied the constant current at frequent intervals and for long periods of time, in which there seemed to be a storage of electricity. A test was made and demonstrated that this was the case.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. George E. Pfahler, Philadelphia; *Vice-Presidents*, Dr. Albert C. Geyser, New York, Dr. Frank B. Granger, Boston; Dr. J. W. Torbett, Marlin, Texas; Dr. William L. Clark, Philadelphia; Dr. Fred C. Tice, Roanoke, Va.; *Treasurer*, Dr. Emil Heuel, New York; *Secretary*, Dr. J. Willard Travell, New York; *Registrar*, Dr. Frederick M. Law, New York.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 15, 1913.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

Cancer Research Institute.—Dr. J. G. ADAMI of Montreal, Canada, read this paper. He said that he found himself in rather an uncomfortable position because he was, despite the best of intentions, able to utter only mere commonplaces. The more he had thought the matter over, the more it had impressed itself upon him that the recommendations he could make were such as were already being carried out at the present moment in New York City. His conclusions must, therefore, be familiar to all who were interested in this subject. He wished to emphasize that the primary object of cancer research was the discovery, not of the cause of malignant new growth, but of the means whereby humanity might be protected against this awful scourge. Keeping this in mind it would be seen that there were two methods of attacking the problem, both logical and scientific, and it was for them to determine which promised the better results. These were the direct and the indirect method. Of the former Ehrlich had afforded a unique and triumphant demonstration in his discovery of salvarsan. This method of research might be most laborious, hundreds of compounds having to be devised, tested, and rejected, but it was a reasonable expectation that gradually certain groups of radicals would be encountered presenting definite specific action upon one or other phase of the particular morbid process, and that eventually some permutations or combination of such substance or substances would be discovered, which would definitely destroy the causative agent within the tissues, or arrest the morbid process without coincident grave injury to the tissues of the individual. This was the method that was being followed by Wassermann and his coadjutors and with a certain measure of reported success as regarded the cancer of animals of the laboratories. It was a purely therapeutical method, even if at the same time purely experimental. It was by means of the indirect method that scientific medicine in their generation had scored its most noted successes. It was the method based on the old Baconian aphorism, "Vere scire est per causas scire"; this was the etiological method. The treatment and control of tuberculosis, diphtheria, and other infections during the past thirty years dated from the moment at which the causative agents were determined, or, failing that (as was the case of yellow fever), dated from the time when, employing rigid analogy, the nature of the disease became realized, that was the detection of the cause threw light upon the mode of prevention of an allied disease. Even in Ehrlich's hands the direct method could not have succeeded but for the previous discovery of the causative agent of syphilis. Applied to cancer he had grave doubts whether the "Ehrlich method" could promise anything of the nature of a full control of the situation. It seemed to him that the majority of scientific workers must be with him when he made the proposition that the indirect method must be that which should be selected and that ideal cancer research must approach the solution of the problem by investigation into the nature of the process of normal tissue growth, into the life history of malignant growths, and so into the cause or causes of neoplasms. Admitted that an institute along the latter lines would be the better and also admitted that despite the labors of a generation of investigators the cause of cancer was still undetermined, how were they to proceed?. The energies of the institute must not be devoted to immediate endeavors to determine the cause, but the position had to be invested from all sides and thoroughly undermined. It was better for an institute to concentrate on one line of attack, though this required no little strength of mind with the full knowledge that it might very possibly turn out to be futile. Cancer research to be well conducted necessitated heavy expenditure, so heavy that the institute was most likely to be of service if it took up one or at most two lines of work. An instance of such concentration of effort might be mentioned in the work of the Imperial Institute for Cancer Research in London which had done valuable work by the accumulation of statistics of cancer incidence in different parts of the world, or that of the Ehrlich Laboratory devoting itself to the transplantation of tumors in the lower animals. If Dr. Gaylord and his associates had failed to discover the causative agent of cancer they had done yeoman service by the methods of exclusion. As a result of such work they had a much fuller knowledge of very many aspects of the problem than they had ten years ago; they were in a position to direct their efforts far more methodically and more serviceably than at any previous period. If, however, there were abundant funds the ideal institute would be in such a center as this, where there were abundant research workers in the various branches of biology and where experts of all orders might be gathered to make a combined attack from many sides. The plan outlined by Columbia College under the Crocker bequest seemed to him admirable, though he was not acquainted with it in all its details. His ideal of a cancer research in a great wealthy city was a combination of an institute such as in Harvard was termed a "commission." There must be a central institute or administration bureau which should contain a library where was collected all modern literature bearing on cancer research, a director's office, and a suite of laboratories and animal rooms for the use of those making investigations under the immediate direction of the head of the institute. There should be a conference chamber, for in his opinion informal conferences had a great value. It was by combined effort that success was most likely to be attained, where individuals were working for the reputation of the institute and for the good of humanity and not for their own glory and advancement. The development of this *esprit de corps* depended essentially upon the influence of the head of the institute. A desideratum of equal value was a hospital or certain wards in a hospital already existing. Failing this, there was danger that the work would become too academic, too remote from practical needs. In such hospitals which offered facilities for the treatment of patients it must be laid down that in return the families must consent in case of death to a post-mortem examination. Beyond these two central sections there was no need to duplicate special laboratories in physics, chemistry, physiology, cytology, and general biology, pharmacology, and experimental therapeutics. Where these were present it was both economical and practical to use them to the fullest. Make the heads of such laboratories members of the executive of the institute and develop the spirit of cooperation so that there may be free consultation between the members of the executive. Let these laboratories be thrown open to those willing and anxious to conduct investigations along any particular line under the direction of the head of each laboratory, the maintenance of the investigators, and the cost of the investigation being paid by the institute. Let the work thus done be brought together and focused by the periodical conferences already referred to. All this depended upon the spirit in which the work was entered into, and above all things on the spirit and enthusiasm of the director.

Cancer Statistics.—Mr. WALTER F. WILCOX of Ithaca, N. Y., read this paper, in which he summarized the conclusions of Messrs. King and Newsholme in their notable paper written in 1893 supporting the conclusion that "the increase in cancer is only apparent and not real," and outlined the objections that had been raised to this conclusion. He called attention to the large body of new evidence which had been accumulated in the intervening twenty years, especially that to be found in the international summaries published by the French government in 1907, and by the Amsterdam statistical bureau in 1911-1912, and in the annual mortality statistics of the registration area of the United States, 1900-1911. After analyzing this and other evidence he concluded that "probably the larger part of the increase, and possibly all the increase, in the mortality from cancer is apparent rather than real. Those who doubt this statement and hold that most of the increase is real may interpret the evidence as showing that the real increase is not at a geometrical or even an arithmetical rate, but diminishes as the death rate from cancer rises, and a few cities, it is already approaching its maximum." and that perhaps in certain limited areas, like Switzerland

Public Education in Cancer.—Dr. WILLY MEYER said he would approach his part of the symposium, "Public Education in Cancer," from the standpoint of the general surgeon. There were three questions of importance, viz.: What was the cause of cancer? Was cancer infectious or contagious, or both? Was cancer curable? These were the questions that were continuously placed before the general surgeon by patients who came to consult him.

1. What was the cause of cancer? He did not think that this was the time or the place to consider this. Still the question had some bearing on the subject of public education in cancer. It was an interesting fact that pathologists in discussing this problem were absolutely opposed to the theory of the cause of cancer being due to a parasite or a microorganism, whereas many general surgeons by clinical observation come to this conclusion. Plain logical thinking in examination of patients could hardly make one think otherwise than that the cause of cancer was a living organism. Take, for instance, a tumor of the breast that did not show the typical symptoms that are suggestive of carcinoma, nor point to a benign tumor. The differen-

tial diagnosis lay between tuberculosis, syphilis, and actinomycosis. We know that tuberculosis is caused by the tubercle bacillus, syphilis by the spirochete, and actinomycosis by the *Actinomyces bovis*—all living organisms. Why should a tumor of this kind, which proved to be carcinoma, have an origin of an entirely different character? Dr. Meyer asked that he be permitted to report two personal observations that had some bearing on this question. In the early nineties the treatment by the injection of methyl violet, particularly fuchsin, was in vogue in patients suffering from inoperable cancer. In one patient with an inoperable regionary carcinoma after amputation of breast this treatment was carried out in the office in the summer. She returned two days later saying that she had an itching sensation over the entire region of the breast. On removing the dressings he found a condition which ordinarily would be diagnosed as an acute eczema. There were innumerable minute elevations near the area that had been injected. It appeared to him as an acute eczema which occurred so frequently under a dressing during the hot weather. He was surprised, in the course of the further observation of this case, to find that every one of these small elevations developed into a carcinoma. He could find no other cause or any other explanation of this phenomenon unless it was that he injected the fuchsin into a nest of local carcinoma, liberating something which was carried by a local artery into the adjacent field in the shape of multiple emboli as in miliary tuberculosis. This something could hardly have been cells. They could not produce by multiplication visible elevations within 24 hours. Further, not long ago Dr. Meyer was called upon to operate upon a patient who seemed to have tuberculosis of the peritoneum, all the symptoms of this condition being presented. He operated and found a large amount of fluid in the peritoneal cavity and the typical signs of tuberculosis, with the one exception, that the minute nodules appeared somewhat more solid than tubercles. A portion of the omentum was excised and he was very much surprised at the pathologist's report, miliary carcinosis. The clinical signs of carcinoma in this case so closely resembled those of tuberculosis that he was confused in his diagnosis. He could not imagine any other cause of carcinoma than a living microorganism and he thought that this would be found some time in the future. If cancer was due to some other cause, biological, chemical or otherwise, why should it happen that after a primary early excision of a cancer, apparently curing the patient, with the same cause persisting, the tumor did not promptly reappear? As mentioned above, many surgeons had come to this conclusion. He said he was very much interested in the report of Professor Georg Klemperer of Berlin, an internist, director of the Institut für Krebsforschung, who also believed that some living organism would be found to be the cause of carcinoma. He said they should just keep on searching and it would be found. He thought it of great importance that the public should be taught and be made to understand that real progress in the cure of cancer could be made much faster if the cause of cancer had been found. Consider the immense progress that had been made in tuberculosis after the demonstration of the tubercle bacillus by Koch and in syphilis after the discovery of the *Treponema pallidum* by Schaudinn. The great trouble with reference to cancer was the fact that there was not sufficient money, no large endowment fund available in every country of the world. If millions of dollars were available for this work on cancer, there would be without doubt rapid progress made in learning its cause.

2. Was cancer infectious, contagious, or both? This was the second important question usually put to the doctor by the patients. One had never seen nor heard of a patient afflicted with the disease conveying it to his wife. Nor did they ever hear of a nurse caring for a patient with carcinoma for months ever becoming stricken with the disease. Dr. Meyer had never heard of a surgeon who, for instance, had injured his finger during the performance of some operation on a cancerous subject ever developing cancer. It did not appear that cancer could be conveyed from one person to another in this way, and therefore the disease could not be considered infectious. An observation he had made was perhaps of some slight interest. He had operated upon a patient years ago by suprapubic cystotomy for a large papilloma of the bladder, cancerous at its base. The disease recurred. The cystoscope showed an involvement of the prostate gland, and the patient was again operated upon and the bladder had to be left open. During the time of treatment he was called to examine the wife and he found she had a carcinoma of the cervix uteri. She was operated on by a gynecologist and died from carcinosis a year later. This was an interesting case to him and one which he often had in mind, although he was unable to state positively that the disease was conveyed from one to the other.

3. Was cancer curable? This third question was always primarily in the patient's mind and he was glad that he could answer this question in the affirmative. Yes, cancer was curable by the surgeon's knife if the growth was radically removed at an early stage. The whole question resolved itself into early diagnosis and early operation. They all knew the clinical aspects in the development of the three stages: (*a*) Cancer was an entirely local disease. (*b*) It was still a local disease with the regionary lymphnodes involved. (*c*) There were metastases.

All had seen that if the cases were diagnosed in time many of such patients could be cured by operation, and absolutely cured. Many observations also demonstrated the fact that cancer in the secondary stage had been cured. Dr. Meyer wished to call special attention to cases of cancer of the breast. Many times had he been called upon to operate on such cases when there was far-reaching involvement of the axillary glands as well as of the infraclavicular glands. Yet these cases, if treated radically, in from forty to fifty per cent., had lived and been under observation for five years and longer. Observations by Wertheim with his operation in five hundred cases of cancer of the uterus showed more than forty per cent. cures. Also the personal statistics of Koeher in resection of the stomach for carcinoma showed twenty per cent. permanent cures. And so it went. Their statistics showed that they were not only able, by means of the knife, to cure carcinoma in the first, but in the second stage. For the after-treatment they were greatly helped by the *x*-ray serum treatment, etc. Therefore, the whole question resolved itself into early diagnosis and early operation. It seemed to Dr. Meyer that it was absolutely necessary to educate not only the public but also the profession in these questions. Undergraduate as well as post-graduate students ought to be taught the importance of an early diagnosis of cancer and its management in special classes, so that they should bear in mind certain symptoms that made these cases suspicious. As one instance he called attention to blood in the urine, vaginal, or rectal discharges. The fact that blood was found in the urine, as a symptomless hematuria, was very important and should always create the suspicion of carcinoma of the kidney. These suspicious cases should be promptly and as early as possible submitted to a cystoscopic examination, especially during the time of the hematuria in order to determine the affected side. The same thing held good in the diagnosis of cancer of the uterus. If there was a bloody discharge from the vagina, especially after the time of the menopause, there should be the suspicion of a beginning carcinoma. This also applied in bleeding from the rectum. This was so often forgotten by the busy general practitioner; if blood appeared in the stools, patient and doctor usually thought first of hemorrhoids. Even if these could not be excluded the individual should be subjected to a digital examination and rectoscopy. Cancer of the esophagus was most benign; the glands in the neighborhood were little involved and there occurred but little in the way of metastases. These patients came early to the doctor because of the difficulty in swallowing, and this occurring many times day after day was the reason that the doctor often had the opportunity of seeing patients with this complaint during the early stage of the disease. The fluoroscope, the *x*-ray sounding with special instruments and esophagoscopy were valuable adjuncts in the diagnosis of cancer of the esophagus and should be used in such cases without delay. If the case was in doubt the surgeon should go ahead and make an exploratory thoracotomy, being prepared for radical work, and so possibly save the patient. Dr. Meyer insisted upon teaching undergraduates and those in post-graduate schools the necessity of making an early diagnosis of these cases of carcinoma. Those who had lived through the times when there was so much discussion on appendicitis knew that patients nowadays frequently came and said, "Take out my appendix." Such was the result of the education of the public in this matter. And the same should result from educating the people regarding carcinoma and the early symptoms of this disease. Of course one should not always blame the general practitioner; many times there would occur carcinoma of the rectum, or of the pylorus, or other organs, and when the general practitioner was consulted it would be too late. Much good was to come from the education of the public. Only today he had seen a woman far advanced with cancer of the breast and she brought as an excuse that the tumor had never been painful. We know that painless tumors

of the breast are very suspicious of being malignant. The public should be educated; they should be told that as soon as blood appeared in the urine, for instance, they should at once consult a doctor and insist upon a diagnosis. It was hardly necessary to call the attention of this audience to how far advanced they were in their warfare against cancer and in the education of the public. It was well known that there were various associations that had taken this matter in hand; committees had been formed for instance in New York for educating the public in this matter. A cancer campaign committee had been created by the Congress of Surgeons of North America last fall, and so on, all working along the same lines and in the same direction. It could not be denied that the work that was already being done was a good one. According to the laws of medical ethics it was hardly permissible for a doctor to write articles for the weekly or monthly magazines, still less for the daily press, in order to so educate the public. But it was a splendid idea and nicely possible for a man like Samuel Hopkins Adams to publish in *Collier's Weekly* articles which tended to educate the public regarding cancer. Dr. Meyer said he was very much interested in hearing in a paper just read by Dr. Cullen of Baltimore how the daily papers had reprinted this article and that the doctor had received letters stating how the husband who had read this article had induced his wife, affected with a tumor, to consult her doctor at once; how another lady had told her husband to do the same. In closing his remarks Dr. Meyer said that they hoped to attain the same results and to save as many lives in patients afflicted with cancer by this general publicity campaign as they had succeeded in doing in those afflicted with tuberculosis.

Dr. Robert Abbe said that a debt of thanks was due to Dr. Wilcox for presenting more comforting statistics than any reviewer of the last decade. Those of Mr. Hoffman, statistician of the Prudential Life Insurance Company, lately presented in Washington, were illustrative of the recent tendency to build up world statistics magnifying the numerical evidence of increase in the cancer plague. Dr. Wilcox's analysis, however, based on smaller groups of well selected statistics, was more in keeping with his own personal observations. Dr. Abbe had felt that in spite of the greater number of cancer cases presenting themselves to the surgeon, coming out of the dark, as it were, the memory of large surgical clinics of thirty years ago recalled about the same proportion of cancer cases as at present which were the subject of clinical lectures. Dr. Adami deserved thanks for the "push" his address would give the work of the cancer research, to study more the cause of cancer than the treatment. Dr. Abbe said that he, himself, had worked more along the lines of treatment, especially local treatment. The remarks of Dr. Meyer that all tendency was now to regard the causation as microbic did not agree with the speaker's observations. The argument of analogy was offered, that "in considering a breast tumor one thought of four possibilities, syphilis, tuberculosis, actinomycosis, and cancer, of which the first three were acknowledged to be microbic, and it was probable that the fourth would be found to be." The fallacy of this was apparent when one showed that easily 95 per cent. of these tumors were disorders of the glandular structure of the breast, wholly unlike any of the others. In addition one saw that Dr. Carrel's growth of cells *in vitro*, carrying on generation after generation of cell development in culture tubes, demonstrated that living cells were not microbes, though they might act like them. A further and very strong argument against the microbic origin of cancer had developed in Dr. Abbe's mind in the fact that radium had a powerful influence on cancer cells, but not through its bactericidal action. The alpha rays emitted from radium were strongly bactericidal, but the gamma were not so. All workers in radium knew that the alpha rays were destructive of tissue as well as bacteria brought in intimate contact; while the beta rays were stimulating, and only the gamma rays were efficient in causing retrograde changes in malignant cells. Hence one must admit that cancers destroyed by radium where no access of alpha rays was permitted were altered by the non-bactericidal gamma rays, which entirely altered their life course and rendered them inert and atrophied. After ten years' study on radium in cancer work it was now evident that men who had sneeringly criticised its beneficent action as limited to small superficial epitheliomas, easily taken care of by other surgical means, must admit that as new evidence was accumulating to show that larger doses than had been hitherto available and new ideas about filtering out burning and stimulating rays by heavy lead or distance filtration had demonstrated a greater efficiency on larger growths and gave promise of a broader field of usefulness. The effects of radium rays on seeds, whose vital forces might be justly compared to that of animal cells, demonstrated that seeds kept for a while close to radium were killed, those at a slight distance were stimulated, and at a greater range they were devitalized and grew with less and less vigor up to a certain distance in comparison with unradiumized seeds planted under similar conditions. This coincided with the results seen in tumors. The failure of radium to cure certain growths urged on the study of cause and effect. It was becoming evident that the use of small or weak doses of radium had been efficient, because of the lack of knowledge of filtration to obtain the more competent penetrating gamma rays in massive doses. This was shown in no better way than by the destruction of epitheliomas caused by the use of Röntgen rays stimulating the skin to develop cancer which the rays of radium cured. This cure was not brought about by any action like cautery or caustic, but by restoring to the aberrant cell growth some lost power of self-control, restoring it to normal lines of growth. It seemed to the speaker that even with the small amount of radium available to the surgeon such progress had been already made to apply this subtle and unique power as gave promise of increasing future value.

Dr. Greenough of the Harvard Cancer Research said that he was more interested in the surgical side of the cancer problem, and was heartily in accord with what Dr. Meyer had said regarding the treatment of cancer by surgical means. He could not accept the views expressed by him in regard to the etiology of cancer. There was no doubt that the public should be educated to understand the meaning of early symptoms pointing to cancer; the general practitioner should be instructed in this matter as well. It was well known that a poor person living in a large city received good treatment; the wealthy were also able to get good treatment and advice, but the bulk of the population living in the country had to depend on less good medical treatment and advice. Only the day before he had operated on a woman for cancer of the breast who had noticed the tumor eight months before consulting him. It was not painful, but she was concerned because of its presence. She had consulted a general practitioner, who had said: "Let it alone until it bothers you." The pathologist's report showed that this was a cancer of the breast. The public should be educated especially along the lines of the early symptoms of cancer in the different localities in the body. The laity should be taught to consult the surgeon or the family physician when any tumor was noted.

Dr. Howard C. Taylor presented the following resolution which was seconded and unanimously carried: *Whereas*, A movement has been started in New York City to educate the people at large on the subject of cancer, and *Whereas*, Sufficient influence in this work by laymen has been shown to raise money to start the campaign of education, Be it *resolved*, That the New York Academy of Medicine give its approval of the movement.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held May 22, 1913.

Dr. George Gray Ward, Jr., in the Chair.

Beneficial Effect of Renal Decapsulation as Shown by Functional Tests Before and After Operation.—Dr. Henry Dawson Furniss reported this case. The patient was a woman who had been married three years, and who soon after marriage had had a plastic operation on both ovaries for a cystic condition. Shortly after this she became pregnant and during the latter months of her pregnancy she had a large amount of albumin in her urine. At the time of labor she had forty-one convulsions, which were followed by loss of memory for three months. Since that time her health had been poor. The urine was constantly of low specific gravity. She missed two periods and since missing the first had felt worse. Phenosulphonephthalein was injected intravenously; 15 per cent. was eliminated in the first hour and none in the second. Because of her previous history, the constant low specific gravity, and the increased headaches, it was decided to empty the uterus, which was done under gas oxygen anesthesia. The patient made an uneventful recovery. While in the hospital the potassium iodide test was given, 0.5 grams being eliminated in forty hours. Twenty c.c. of 10 per cent. lactose injected intravenously was eliminated in four hours; with phenolsulphonephthalein, 0.6 mg. having been injected intravenously, five per cent. was eliminated in the first hour and only a trace in the second.

The blood pressure was 135. The patient after returning home had a great deal of headache and did not improve as she should have done. Under gas oxygen ether, Dr. Lloyd operated on the left side and Dr. Furniss on the right, both kidneys being decapsulated. So far as could be determined they appeared to be normal in size and appearance; the capsule was not thickened or adherent. Within four days after this the headache had disappeared and the patient felt better than she had for a year or more. A week after the operation phenolsulphonephthalein was again injected intravenously and the elimination during the first hour was 90 per cent. and 10 per cent. in the second hour; from this they knew that too much had been given. A second test showed 65 per cent. in the first hour and 15 in the second. Two weeks after the same results were obtained. The patient was slow in regaining her strength, but complained of no more headaches, and the phenolsulphonephthalein test given about six weeks after the operation showed an elimination of 55 per cent. during the first hour and 10 per cent. during the second. The only time that he had obtained any albumin was immediately after the first operation and then there was a very large amount with many hyaline and granular casts.

Dr. Harold Capron Bailey asked Dr. Furniss what were the indications which caused him to operate and whether the benefit was theoretical or actual. He could not understand the indications in the case which called for this operation.

Dr. Henry Dawson Furniss, in answer to Dr. Bailey's inquiry, said that the patient had had eclampsia and had never been well since, suffering from headaches, which were constant, and there was a low elimination of phenolsulphonephthalein, which showed that there was some derangement of the kidneys. After the operation the elimination of phenolsulphonephthalein which previously had been about 5 per cent. during the first hour increased to 65 per cent. Since the operation the patient had been free from headaches and felt better than she had done for two years. He suspected a contracted kidney and thought some operation should be done.

Specimen of Early Ectopic Gestation.—Dr. George Gray Ward, Jr., presented this specimen. The patient from whom the specimen was removed was twenty-five years of age and had been married five months. Her last period was on November 26 and the following one was four days late, and was more painful than usual, and spotting continued. As she had some pain in the left side an ectopic gestation was suspected. A vaginal section was made on January 24 and free blood was found in the abdomen; an abdominal section was then made and a very early unruptured pregnancy found. The uterus was of the infantile type and contained an interstitial fibroid, the size of a small marble, in the fundus. As the husband had an uncured syphilis and the patient herself had a tuberculous history, and as there was a uterine fibroid, a supravaginal hysterectomy was done, leaving the right ovary *in situ*. The appendix was found to be tuberculous and was removed. A nodular mass was found in the wall of the ileum, which was evidently tuberculous; therefore, a resection of the gut was made and an anastomosis completed. The patient made a good recovery.

Epithelioma of the Clitoris.—Dr. George Gray Ward Jr., reported this case. The patient was 46 years of age, had been married 30 years, and had had six children, all normal labors and no miscarriages. A year previous to presenting herself she noticed a small pimple in the region of the clitoris which had steadily increased in size. Three months before entering the hospital the growth had ulcerated. The patient was cachectic and a blood examination showed hemoglobin 30 per cent., and 1,150,000 red cells. There was no leucocytosis, and the patient complained of loss of strength and pain. The size of the growth was about that of a silver dollar, the clitoris, vestibule, and a portion of the left labium being involved. There was a complete excision of the growth together with a considerable area of normal tissue down to the periosteum of the pubic bones. The edges of the wound were brought together with silkworm sutures. The patient made a normal recovery and the blood picture rapidly improved.

Occlusion of the Cervix and Partial Obliteration of the Uterine Cavity Following Puerperal Sepsis.—Dr. E. A. Bullard of Brooklyn reported this case. The patient was sent to the Long Island College Hospital on August 27, 1910, in a desperate condition during her fourth labor. On August 27 a stillborn baby was delivered. Puerperal sepsis and neuritis affecting both legs ensued. The sepsis was severe and the patient was in a more or less dangerous condition for a month. The treatment of the sepsis consisted of intrauterine douches during the first few days, the Murphy drip, and stimulation when required. The patient finally recovered and was discharged on December 25, though she still has some leucorrhea and a slight neuritis. About two years later she returned in apparently perfect health except that she had never menstruated since leaving the hospital. Every four weeks she had the menstrual molimen for a few hours, but no pelvic pain and never a drop of menstrual fluid. Examination revealed a slight cystocele and a moderate laceration of the perineum. The cervix was normal in size and mobile, but very hard. The site of the external os was replaced by scar tissue. A sinus which admitted a probe for about one-half an inch was seen on the right side of the cervix. Bimanually the uterus seemed about normal in size, retrocessed, but mobile. There were adnexal enlargements and no tenderness was present. The cervix was split up bilaterally. The little sinus was found to be about one-half inch in length, with a blind end. An opening was made into a cavity in the left side of the fundus; this cavity was about one inch long and one inch wide, and contained a little mucus, but no blood. It was not curetted for fear of destroying whatever chance the patient might have of menstruating. The cervix was sewn up and a hard rubber stem pessary was put into the uterine cavity emerging into the left lateral fornix. The abdomen was opened through a low median incision and the uterus was found to be about normal in size and appearance. The tubes were occluded in their inner thirds. The ovaries appeared about normal and one contained a Graafian follicle about to rupture. The patient made an uneventful recovery and left the hospital in about ten days. Three weeks later she returned and it was found that the sutures holding the pessary had cut through and the pessary had been lost. However, a sound could be passed into the uterine cavity. The patient was told to come to the clinic every other day in order to have sounds passed, but she neglected to follow these instructions and by the end of a month the little canal was closed up. At no time after the operation was there any suggestion of a menstrual flow. He had seen the patient at intervals of from two to four months and she was always in the same excellent health. He believed that the sepsis was responsible for the entire destruction of the endometrium, the partial obliteration of the uterine cavity, and the total occlusion of the cervical canal. It was interesting to note that so little damage had been done to the tubes, and no discoverable harm to the ovaries. In an extensive search of the literature he had found that atresia of the fundus or cervix was much more rare than that of the vagina. He had found the records of about 100 cases. The etiology of these cases was interesting, the condition being attributed to puerperal sepsis in 18 cases, to atmocausis in 10 recorded cases, to cicatricial contraction of obstetric lacerations in 12, to congenital causes in 13, to acquired but unknown causes in 9 cases, to the application of caustics to the uterus and cervix in 14, to defective amputation of the cervix in 3, to the continuous use of the pessary for many years in 2, to tuberculosis of the fundus in 1, and after a severe leucorrhea of gonorrheal origin in 1. In the early days of the use of steam for controlling uterine hemorrhage Pincus, Duhrssen, and others had several cases of partial or complete obliteration of the cervical canal until they learned that about thirty seconds of atmocausis should be the maximum time. Most of the congenital cases were of the cervix only and were cured by trachelorrhaphy or puncture of the cervix. In only a few of the septic cases was the endometrium hopelessly destroyed, as in the speaker's case.

Dystocia Following an Interposition Operation, Complicated by Placenta Previa.—Dr. George W. Kosmak reported the case of a multipara, seven months pregnant, who was admitted to the Lying-In Hospital April 19 last with a history of sudden bleeding without cause which began a few hours previously. She was not in labor. An examination made about two hours after the hemorrhage began showed the vagina filled with large blood clots. A search for the cervix disclosed the same at the extreme upper end of an elongated vagina in a position above the brim of the pelvis. It was very rigid, admitted one finger, and the canal was about two inches long. The cervix could not be pulled down and further exploration showed the presence of a centrally situated placenta previa, which had separated from the lower uterine segment. In view of the necessity of an immediate delivery, as the patient was bleeding freely, an abdominal cesarean section was decided on as offering the most favorable outcome for the patient. The fetal heart could be heard, but it was faint. A gauze pack was temporarily inserted and the patient prepared for operation. After the removal of the gauze a vaginal douche of plain sterile water was given on account of the previous vaginal manipulation. Cesarean

section was done and a small fetus, which breathed for a short time, was extracted by the breech. The placenta was found to be almost separated in the lower segment of the uterus over the cervix. It was readily extracted with the membranes. There was comparatively little bleeding and prompt contraction occurred. The patient was returned to bed in fairly good condition. She made a good recovery and was discharged from the hospital in three weeks, although she was up on the tenth day. Her anemic condition was largely benefited by keeping her on the roof of the hospital during the greater part of the time. A more complete history obtained subsequently showed that the patient was thirty-five years old, married seventeen years, had had six children, and four early miscarriages. In her fourth confinement instruments were required because of a large child, and she dated her uterine prolapse from this time. It was evidently complete, as she stated that the ulcerated cervix projected entirely beyond the vulvar opening. She was operated on in August, 1912, and made a good recovery following the interposition operation. Her last regular period was normal. During her pregnancy she was well except for an inability to urinate readily and catheterization had to be resorted to several times. She stated that she had worked all through her pregnancy and did not observe anything abnormal until she began to bleed on the morning of her admission to the hospital. An examination made on May 21, 1913, showed her to be in good general condition, with but a small abdominal scar. The uterus was in a very good condition, with the fundus below the bladder and well involuted.

This case was reported by Dr. Kosmak as showing the possibility of a dystocia following this operation. It was unfortunate that the condition was complicated by the presence of a placenta previa, although with the lack of mobility of the cervix it was doubtful whether labor could have taken place at term without resort to interference and with the greater distention of the uterus at this time a rupture could readily have taken place. Sterilization of the woman was not permitted at the time of the operation because her condition of shock prevented any extension of the time necessarily required by the same.

SECTION ON MEDICINE.

Stated Meeting, Held May 20, 1913.

DR. JOSEPH C. ROPER, CHAIRMAN *pro tem.*

Adherent Pericardium—Exhibition of Specimens and Cases; also One Case of Cardiolysis.—Dr. GEORGE MONTAGUE SWIFT read this paper and showed specimens and cases from St. Mary's Free Hospital for Children. By adherent pericardium he understood a condition following an acute process involving the external and internal surfaces of the pericardium, and the adjacent tissues in the mediastinum, causing adhesions to the chest wall as well as to the soft tissues. The term chronic pericarditis, adherent pericardium, mediastinitis, mediastinopericarditis were used practically synonymously. Between January 1, 1909, and January 1, 1913, there had been at St. Mary's Free Hospital for Children 30 cases showing this condition, and there were admitted annually 750 medical cases. Since October 1, 1912, there had been eight cases of chronic and three cases of acute pericarditis. These figures showed that the condition was not an infrequent one and that pericarditis occurring among children was common. The average age was found to be about nine and a half years.

In speaking of the etiology he said that several investigators had shown that pericarditis was due to bacterial infection; there were found diplococci, pneumococci, streptococci, staphylococci, and mixed infections. They had not met with any cases of tuberculous infection. Different germs probably caused some variation in the character of the effusion and the later developments of the condition must also be influenced by the character of the exudation. The important fact was that the disease was due to an infection and that the infecting organism probably gained entrance to the circulation through, most commonly, the tissues of the nasopharynx, tonsils, gums about decayed teeth, etc., and also from any point of infection. This was a most important point as regarded prophylaxis, as well as treatment. It was essential that they should seek to remove all possible sources of infection, and abandon the idea of "rheumatism" as a cause or, indeed, as meaning anything. Symptoms and signs of chronic pericarditis, adherent pericardium, were mainly those of dilated heart; the one characteristic sign, present, however, only when the heart muscle was in fairly good condition, was a retraction of the intercostal spaces over the heart during systole. One found also a bulging of the precordial area, frequently an impulse almost in the axillary line, which impulse was not altered by changing the position of the subject. In cases where the heart muscle was weak there might be an impulse. There was also great enlargement of cardiac dullness. By auscultation, ordinarily one heard loud double murmurs, but in the chronic cases there was nothing especially characteristic. In many of the cases autopsy had shown the valves of the heart to be without lesion, though the murmurs during life were loud and persisting, and apparently valvular. The *x*-ray plates had been of the greatest aid in diagnosis. Several cases unrecognized by ordinary methods had been demonstrated by Dr. Busby to be cases of adherent pericardium. Without the *x*-ray one might suppose that he had to deal with a heart enlarged only from valvular disease. If the individual survived the acute process, as many did, the later course and development must depend upon the location and character of the adhesions formed, and the extent of the involvement of the myocardium. In many cases there seemed to be a continuing growth of connective tissue which gradually by its contraction pinched the nutritive blood vessels and a gradual degeneration of the heart muscle followed, so that upon autopsy one found a mere bag of connective tissue with almost no remaining heart muscle. In other cases there was such a retraction of the new tissue forming the adhesions that the large vessels in the chest were pulled upon so that there was much interference with the return circulation, and hence great enlargement of the liver and fullness of the veins of the neck. There might be an excessive cough due to the involvement of the laryngeal nerve. The possibility of signs produced in this way were many; in one instance a boy of nine years had a bruit over the base of the heart, suggesting the presence of an aortic aneurysm, but the *x*-ray showed no dilatation of the aorta. Though the ultimate prognosis was bad one of the patients exhibited appeared to be in excellent condition; three years ago his state was most deplorable.

One patient in private practice whom he had known for twenty-seven years had such firm and extensive adhesions as to embarrass the movements of the heart and also the movements of the chest wall and diaphragm in respiration. Operation had been devised by Brauer to free some of these adhesions and had been done by several surgeons with varying degrees of success. During the past winter one of the cases in St. Mary's was adjudged to be an appropriate case for operation, and this operation of cardiolysis was done by Dr. Dowd. The case was exhibited, but Dr. Dowd did not think that so far it had materially benefited the boy.

A Case of Graves' Disease with Scleroderma and a Positive Wassermann Reaction Treated with Salvarsan.—Dr. H. F. L. ZIEGEL read this paper. (See MEDICAL RECORD, Vol. 83, page 1124.)

Dr. HOWARD FOX said that he had first seen the patient about two years ago, when she had come to the clinic to be treated for scleroderma. He had made a Wasserman test, which proved to be negative. He had made the test because at that time the possibility of a connection between scleroderma and syphilis was being discussed. In a number of cases of the generalized form of scleroderma, positive Wassermann reactions were obtained. This applied particularly to the sclerodactylia type of the disease, which began in the fingers and extended up the arms, and was at times associated with Raynaud's disease. In the localized type of scleroderma, the so-called morphea, he had always found the Wassermann reaction negative, an experience which practically coincided with that of others. He was not inclined to think that the skin lesions in this case stood in any relation to syphilis. Whether the generalized type of scleroderma was specific in origin or whether it represented another class of diseases in which at times non-specific inhibitions were obtained he could not say. Dr. Fox thought that the chief point of interest to the members of the medical section was doubtless the improvement in the symptoms of Graves' disease that had followed the injections of salvarsan. From this standpoint the improvement of the scleroderma was of special interest. This could be seen in the photographs which he had taken at an interval of two years. The large area of solid infiltration had broken up into small islands of sclerodermatous tissue. Of course, such an improvement might have been spontaneous. As, however, the treatment of scleroderma was notoriously unsatisfactory, the improvement shown after Dr. Ziegel's treatment was at least interesting and suggestive.

Books Received.

Miscellany.

Literature and Medicine.—J. W. Ballantyne believes that there is room for a periodical that would deal with the literary aspects of medicine and the medical aspects of literature. Among the many topics that claim attention would be the question of how far a training or a partial training in medicine influenced the afterlife and the literary output of certain distinguished writers. To this group belong Conan Doyle, Samuel Smiles, Goldsmith, James Hutchison Stirling, Andrew Wilson, and Gordon Stables. Another group includes men who continued to practise medicine and surgery, and who nevertheless attained positions of literary eminence. Such men were Sir Thomas Browne, Oliver Wendell Holmes, John Brown, and Mark Akenside. There were a number of literary men who had a smattering of medical knowledge, men who had been no more than first- or second-year students. To this class belonged Keats, Southey, and Abraham Cowley. Another important aspect of literary medicine is furnished by those books for medicine which are also literature. Besides, general literature has certain medical aspects. One of these is the frequent use and abuse of medical metaphors. Shakespeare was particularly adept in his medical allusions. There are works full of medical facts, such as Burton's "The Anatomy of Melancholy," which were written by authors who were not doctors. It was said of Burton that he was "by profession a divine, by inclination a physician." John Wesley was no doctor, yet his "Primitive Physic," written in 1747, reached its thirty-sixth edition in 1840. Defoe's "Journal of the Plague Year" was written by a wholly literary man. Goethe made contributions to anatomy, physiology, and embryology.—*Edinburgh Medical Journal*, August, 1913.

A Clear View Through a Wet Wind Shield.—Harold Snipe describes in the *British Medical Journal*, September 20, 1913, a method of obtaining a clear view through the wind shield of an automobile even in the wettest weather. The following solution is applied to the wind shield:

℞ Sodium chloride, 1 dram.
Water, 1 ounce.
Glycerine, 2 ounces.

A little of this is placed on gauze and wiped over the glass in a very thin layer, but always in a downward direction. This is a boon on a wet night on a dark road.

Napoleon and Hypopituitarism.—Of late there has been considerable speculation as to the actual cause of death of Napoleon Bonaparte. Chaplin's recent study has tended to confirm the original official report that the exile of St. Helena died from cancer of the stomach, unrecognized during life. Keith, however, has advanced the view that Napoleon died as the result of a hepatitis and perihepatitis secondary to some form of undulant fever. Still another theory has been proposed. Leonard Guthrie in the *Lancet*, September 13, 1913, points out that there is evidence that Napoleon towards the end of his career suffered from a deficiency in the secretion of the anterior lobe of the pituitary body. The evidences of this form of hypopituitarism were genital atrophy, sexual alopecia, skeletal and tissue changes of feminine type, and lowered body temperature. Obesity and a sluggish metabolism indicated a deficient activity of the posterior lobe.

THE CURE THROUGH GENITOURINARY SURGERY OF ARTHRITIS DEFORMANS AND ALLIED VARIETIES OF CHRONIC RHEUMATISM.*

By EUGENE FULLER, M.D.,

NEW YORK.

The solving of surgical problems through experimental or, perhaps better, pioneer work is the interesting or absorbing feature of one's professional life, while the work along beaten paths is the bread-winning feature. Many confine themselves to the beaten track and never tread on a new path until it has been, as it were, asphalted. Such men are perhaps the more popular from being the least criticised. Still, if a surgeon does not interest himself in new problems he rarely preserves his alertness, but tends to become stale and lacking in resourcefulness.

As many of the profession know, I have for a considerable period devoted much of my time allotted to research to surgery in connection with the seminal vesicles—important organs which hitherto had received almost no special attention. As a result, at the present time, of an operative experience in connection with 346 cases, much of the work which originally was experimental and research is no longer so but has been relegated to the beaten path of surgical routine. In numerous articles I have, from time to time, acquainted the profession with the various groups of subjective symptoms which have been found to be curable as a result of the removal of lesions connected with the seminal vesicles through a resort to seminal vesiculotomy. The present paper is to deal with one group only of cases representative of a very chronic and advanced form of rheumatism which I have found to be likewise curable. My experience with and knowledge of these cases came as a sequel to preceding work in connection with typical gonorrheal rheumatism, so-called, in its acute forms (*Annals of Surgery*, June, 1905; Medical Record, October 30, 1909, and June 15, 1912). In the last paper referred to, entitled "The Management of Gonorrheal Rheumatism," read at the 1912 meeting of the American Urological Association, much of this subject was considered, and, should one be interested, I would recommend a reading of that article, since the attempt will here be made to supplement rather than to reiterate the preceding communications. In that article much fault was found with the term gonorrheal rheumatism, especially as applied to the more chronic forms of the affection, and the opinion was positively expressed that a toxemia independent of the gonococcus systemically absorbed from infected seminal vesicles was the cause for such forms of rheumatism.

Up to that time, owing to the depth of the wound leading to the opened seminal vesicles, and to its narrow path, I had found it difficult to obtain accurate smears from the interior of the sacs. Since then, however, thanks to Dr. Bradbury, assistant visiting physician at the City Hospital, I have employed a smear carrier enclosed in a glass tube, the further end of which, as the tube is introduced, is plugged. A thread attached to the plug is pulled as the end of the tube enters the open seminal vesicle, after which the smear carrier is quickly pushed down so as to wipe the interior of the sac.

Dr. Larkin, pathologist to the City Hospital, in making cultures from these smears, has not discovered the gonococcus in these chronic conditions, but uniformly the streptococcus, and on one occasion a streptococcus of a peculiar pink or reddish hue, from which he made many cultures, all the progeny being characterized by the same coloring. The gonorrheal fixation test has also been tried on very many cases representative of acute, chronic, and intermediate grades of rheumatism associated with gonorrhea, and subsequent to gonorrhea. In the acuter forms of the affection, the test was usually positive, and oftentimes in cases showing a marked tendency to chronicity the test would be positive a year or two after the time, according to the clinical history, the gonorrheal infection had occurred. In one case a weakly positive test was found somewhat over five years after the stated occurrence of the infection. In most chronic cases, however, where there is evidence that a recurrence of gonorrheal infection has not occurred, seminal vesiculitis persisting as a resulting lesion, the fixation test was found to be negative. The streptococcus could always be counted upon as existing in such cases.

When one considers that this genital lesion lies next to the rectum, the natural habitat of the colon bacillus, it is plain that such infection must finally take place by direct transmission through the intervening tissues, even though it may not have apparently ascended by way of the ejaculatory duct. In certain old chronic cases a marked seminal vesiculitis and characteristic rheumatism would be found, wherein all questions as to the previous existence of a gonorrhea would receive negative answers. In such cases it was observed that the rheumatism would disappear with the post-operative disappearance of the seminal vesiculitis, just as in the cases wherein there was a preceding history of gonorrhea. It is, of course, probable that in some of these latter cases—and perhaps in most of them—gonorrhea had previously existed, notwithstanding answers to the contrary; still, in some of them it seemed most likely that the clinical answers were correct, and in a few it was highly improbable that they were not so.

*Read May 6, 1913, at the Washington meeting of the American Association of Genito-Urinary Surgeons.

In the diagnostication of rheumatic conditions gonorrhea as an etiological factor is commonly dismissed from consideration if not then actually present, or if it had apparently not been present during the incipiency of the affection. In order to avoid error it is advisable, especially while considering chronic cases, to determine the condition of the seminal vesicles as a matter of routine.

Prognosis as regards the cure of absorptive rheumatism through seminal vesiculotomy is decidedly good. In the paper on "Management of Gonorrheal Rheumatism," MEDICAL RECORD, June 15, 1912, the following statements bearing on this point were made: "In the article already referred to, which appeared in the MEDICAL RECORD, October 30, 1909, I reported my first 126 cases of seminal vesiculotomy. Of these 35 represented cases of rheumatism. Since then I have performed seminal vesiculotomy 125 more times, so that at present my total operative cases number 251. Of these last 125 cases 87 represented rheumatism. With most of these the rheumatism, acute or chronic, was of a very severe grade, and it was for the relief of the rheumatism only that seminal vesiculotomy was performed. A minority of the cases had other clinical symptoms due to seminal vesiculitis, coexisting with rheumatism, as a reason for operation. In this last series a much larger proportion represented rheumatic conditions than pertained to the first series. This is largely because rheumatism is the clinical symptom of seminal vesiculitis which usually, by incapacitating an individual, brings him to hospital, and, in my experience at the City Hospital, when those suffering from rheumatism see the rapid cures resulting with little post-operative discomfort in those who have been subjected to seminal vesiculotomy, there is such a scramble for operation that no time has to be wasted in persuasion. Out of 251 cases there has been no mortality, so argument against the operation on that score cannot be very impressive. In my last series the results with rheumatic cases have been uniformly good. I attribute the better results in the second series to a more thorough performance of the operation and to improved post-operative details."

Since the preceding report of last year I have performed seminal vesiculotomy 95 times, making my present total of cases 346. In this last series the operation was undertaken for the relief of rheumatism in 69 cases. In connection with these last cases I had one death, my first fatality. In this instance the subject was an alcoholic with granular kidneys. Death occurred two weeks after operation, due to renal disease. I was aware of the fact that this patient was a bad surgical risk before operation was performed, and had I in mind only the avoidance of the risk of possible post-operative death, such a case could well have been denied operative relief. Many of my successful cases, however, have apparently been much worse surgical risks than this one. In these bad surgical risks it has been found that, as a rule, the cure of complicating rheumatism has been of such systemic benefit that a recovery to a marked degree from independent coexisting ailments has frequently followed.

In this last series of 69 cases, between twenty and twenty-five have represented extremely chronic or most advanced conditions of rheumatism. In a number of them sufficient time has not as yet elapsed since operation for the end result to be attained. The acuter cases, aside from the one who died—and that patient stated a week after his operation that all his rheumatic symptoms had disappeared—were all discharged from hospital in a very satisfactory condition. All were told to report at the clinic after discharge in case any disturbing symptoms occurred. Very few were seen afterward in clinic.

Of the chronic cases of this last series, there is one, wherein true bony ankylosis of both hip joints had occurred, in which I am doubtful if the operation of seminal vesiculotomy has done any good. This is the first instance in which I have found true bony ankylosis instead of firm fibrous adhesions. I have had many other cases, however, wherein bony ankylosis had supposedly existed. In all such instances, forcible manipulation previous to operation, while the patient was fully under the influence of an anesthetic, had demonstrated that no true bony ankylosis did exist, tendonous adhesions alone accounting for the fixation. Whereas in acute cases a cure of rheumatic complications following operation is rapid, it is natural in connection with chronic ones that the end result should be slower. In both phases of the disease, the operation, by draining the septic focus, puts an end to systemic toxemia. In the chronic cases, the toxemia may produce certain secondary lesions or results, which remain after the sepsis has disappeared, and it is not until these secondary lesions have vanished that a cure is usually reckoned.

The secondary lesions which require the most time for post-operative resolution are firm, fibrous adhesions of joints and tendon sheaths, exudations of hard plastic lymph, and marked muscular atrophies. In the chronic cases, where the feature of the lesions is fluid exudation into movable joints, complete cure following operation is rapid. In very chronic cases, wherein the lesions resulting from the systemic toxemia are most marked, it usually requires six months, and it may require two years before the final benefit following operation is attained. Formerly, in connection with chronically fixed joints and atrophic muscles, I prescribed massage and joint manipulation at the end of a month or thereabouts after operation. Experience has shown, however, that it is not advisable to prescribe such after-treatment. Much better results are attained when the patient is left to himself, with directions to gradually exercise and move more and more the parts involved. Massage and movements, when not applied by the patient himself, are apparently apt to be overdone, and consequently productive of too much reaction.

As the operation of seminal vesiculotomy is productive of a cure, by reason of the fact that it frees the individual affected of the septic focus accounting for the rheumatism, it naturally follows that the operation, to be successful, must accomplish its purpose. In my first series of 35 cases results were not as uniformly good as those attending later operations, for the reason that septic foci in these early cases were not treated surgically as radically as in the later operations. This was observed chiefly in connection with chronic cases which call especially for radical surgery.

As I have frequently remarked, a temporary and usually slight return of rheumatic symptoms may show itself a month or six weeks after operation, in cases wherein all such symptoms had promptly disappeared after operation. This simply means that the external tract of the wound has healed pre-

maturely before the deep portions have been thoroughly drained, the toxins so pent up accounting for the rheumatic recurrence. On this account, it is very important not to allow such premature external closure but to maintain drainage tubes in position until the deep portion of the wound has thoroughly granulated and healed. Another essential surgical point lies in a thorough and free opening throughout their entire length of the affected seminal vesicles. In very chronic conditions the sac walls are lined with pyogenic granulation tissue. Such tissue should be removed. Then, again, in such conditions wherein there exists much periseminal vesicular sclerosis, it is necessary to free the organs from surrounding adhesions, and oftentimes to make a counter incision into the sac opposite the cut which first opened the cavity. This counter incision divides the sac wall lying next the floor of the bladder, and should it be made to include tissue beyond the sac cavity it is probable the bladder cavity would be opened. Although care should be exercised not to cut beyond the sac cavity, thus opening the bladder, still it not infrequently happens that urine leakage to a greater or less degree will take place into this genital wound, even though the bladder floor has not been incised. Such an occurrence as this may be observed in cases where the bladder wall lying over the sac has become adherent, infiltrated, perhaps riddled with sinuses, or attenuated by chronic sclerosis—all such lesions having extended to the bladder wall from the primary focus in the seminal vesicle. Urine leakage of this character does not interfere with a final good result from the seminal vesiculotomy. Sometimes, in cases such as these, where the bladder wall in contact with the seminal vesicle is extensively involved, the necessary surgical manipulation of the part after the counter incision into the seminal vesicle has been made will result in a tear or perforation through the bladder floor sufficient to admit a catheter of 20 French calibre, or thereabouts. If a perforation of such size occurs, post-operative drainage of the bladder should be established by the passage through the opening of a catheter. The treatment in this manner of cases so complicated led me on a number of occasions to drain the bladder along this post-prostatic route, independently of conditions in the seminal vesicles. In such cases, the incision through the floor of the bladder was made in the middle line between the seminal vesicles. Consequently, in this procedure the genital organs are not disturbed. I have published an article entitled "Post-prostatic Cystotomy," MEDICAL RECORD, October 22, 1910, devoted especially to the subject.

Another important operative feature after the diseased area has been thoroughly exposed is the introduction of the packing. Each seminal vesicle should be treated with a separate long strip of gauze, which should be so crowded in as to firmly and completely fill the open cavities. It is over this packing and between it and the rectal wall that the drainage tubes are placed. (For a description of the operative technique, see MEDICAL RECORD, October 30, 1909). In the way of description, a brief clinical record of a number of cases will be given, which illustrate different phases of chronic rheumatism.

CASE A.—Man, 42 years of age, came to me four years ago. His rheumatism commenced sixteen years previously and had been so progressive that for the last seven years he had most of the time been bedridden. He had largely lost the motion and use of his fingers, and both wrists were fixed by adhesions, as were also the elbows. Ankles and knees were likewise involved. There was partial movement only of the hips. The spinal vertebræ were stiff and immovable, and the ribs so fixed that breathing was wholly diaphragmatic. The neck was fixed. There was a history of gonorrhea twenty years ago. Urine contained some pus and bacteria, chiefly streptococci. For his bladder condition there had been much treatment without beneficial results. There was a marked seminal vesiculitis, very sclerous in character, and besides this there was a deep false passage leading from a tear in the floor of the membranous urethra under the anterior margin of the prostate. Seminal vesiculotomy was first performed, and two months later a perineal cystotomy for the cure of the false passage. Six months after the seminal vesiculotomy the patient had gained thirty pounds and had in a large degree recovered the mobility of his joints. One year after the operation he was actively at work, and has continued able-bodied ever since.

CASE B.—Man, 47 years of age, transferred to my ward at the City Hospital a year and a half ago from the medical side where he had been for three years confined to bed or at most sitting in a chair beside his bed. Patient could not walk, owing to rheumatic involvement of both feet and knees. These joints were also greatly swollen and there was much fluid in both knees. On first inspection one would be apt to think the case one of dropsy. He had been a sufferer from rheumatism in feet and knees for ten years. For the first seven years he had been able to work part of the time between exacerbations of his affection. There was an indefinite history of gonorrhea fifteen years, or thereabouts, before. There were no genitourinary symptoms complained of. Examination showed the existence of a marked seminal vesiculitis. Seminal vesiculotomy was performed, resulting in a quick cure of the existing rheumatic conditions, together with the accompanying swelling. In less than three months the patient left the hospital fully recovered. The rapidity of the cure in this case was due to the fact that there was no fixation of the joints and no resulting muscular atrophy.

CASE C.—A young man, 22 years of age. This and the following case are reported because of the severe and precocious type of the affection. In these cases in a few months conditions were reached which in many, and in fact, in usual conditions would only have been observed where the affliction had progressed for years. The patient was brought to the hospital in an ambulance. The left thigh was sharply flexed and immovable. The vertebræ were also fixed. The right knee and ankle were involved. The least movement affecting any of these parts caused so much suffering that none was attempted, the result being extensive bedsores. There was much emaciation. The rheumatism commenced four months ago, having been preceded two months by gonorrhea. There was a marked and active seminal vesiculitis. Rapid and radical relief as regards pain followed seminal vesiculotomy. The patient was up with fair motion a month after operation. In two months after operation he was discharged able-bodied and well, and has so since remained.

CASE D.—Young man, 23 years of age. Progressive and precocious rheumatism for three months. In this case, there was a general involvement of joints and tendons. On entering the hospital the patient could not move except slightly in any direction, nor could he feed himself. He could open his jaws but little, and so could not chew food. There was great emaciation, bad color, and a marked appearance of cachexia. There was a history of gonorrhea between two and three months before the commencement of the rheumatism. The seminal vesicles were rigid and sclerous, and bound down by outside adhesions, showing that the septic process had extended extensively into the surrounding fibrous tissues. The condition of this patient was so grave that no one thought he could live longer than two weeks with existing conditions remaining. Without loss of time, seminal vesiculotomy was performed, a quick cessation of symptoms resulting. A month after the operation the patient had gained twenty pounds. In two and a half months after operation he left hospital fully recovered and able to work. This patient could have been discharged much sooner, but was kept for observation.

CASE E.—Man, 46 years of age. There was marked swelling of the right knee with some flexion and immobility of the joint. There was no fluid in the joint but a hard boggy infiltration. There was much pain on manipulation. The appearance presented was that usually classed as "white swelling." The use of the right hand had been lost by a progressive rheumatic affection which had caused a fixation of the wrist and the digital joints. Tendinous

adhesions had so drawn the fingers as to cause considerable deformity. There was no evidence of gonorrhea in the clinical history or as the result of examination. There was, however, a marked sclerous seminal vesiculitis. Seminal vesiculotomy was performed. Gradual and progressive resolution quickly commenced in connection with the joint

Fig. 1.—Case F. From a photograph by Dr. H. H. Janeway.

lesions. Six months after the operation the patient had entirely recovered aside from the fact that the movements of the right fingers and wrist were slightly less free than those of the left.

Case F.—Man, 30 years of age. There was fixation of the right hip with much contraction and deformity, as seen in Fig. 1, Case F. These conditions had existed for over a year. There was a history of gonorrhea three or four years previously. In the patient's opinion, that affection had caused him little trouble, and had promptly gotten en-

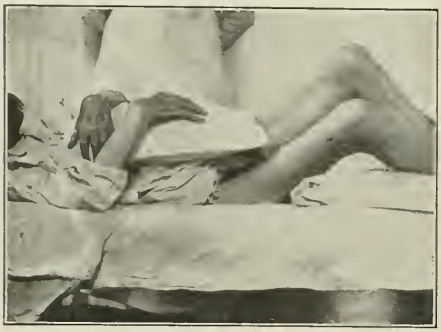

Fig. 2.—Case H. From photograph by Dr. H. H. Janeway.

tirely well. There was considerable discussion as to the true diagnosis in this case. As a chronic sclerous seminal vesiculitis existed, these organs were subjected to surgical operation, followed by a progressive and gradual improvement in the condition of the hip. Four months after operation patient could move hip joint freely, and stand straight. He then walked easily, with scarcely a difference between the movements in the affected and the corresponding joint.

Case G.—Man, 35 years old. Complete fixation of lumbar, dorsal, and cervical vertebræ. The ribs were also fixed and immovable. The back was not bent, but was perfectly straight and rigid. There was complete fixation of the head at a considerable lateral angle. Owing to the fixation of the ribs, the breathing was wholly diaphragmatic. There was complaint of great pain the length of the spine, together with headache. When first seen, the patient was wearing a steel frame jacket to guard him against jarring sensations. His rheumatic affection had begun four years previously and had been steadily progressive. There was a history of gonorrhea seven years before the commencement of the rheumatism. It was supposed that the gonorrhea had ended in resolution in two or three months. Marked sclerous seminal vesiculitis was found to exist. Seminal vesiculotomy was performed, followed by a gradual and progressive resolution of the rheumatism and the resulting joint fixations. When last seen, two months ago, one year after operation, the patient was regularly at work as a laborer. The ribs were movable, the head could be freely rotated. There was still some remaining fixation in connection with the lumbar and dorsal vertebræ. Headaches and pain had not been a feature since operation.

Case H.—Man, 47 years of age; bedridden and unable to move or to feed himself. There was much stiffness or fixation of all joints. The only joints in the whole body which could be functionated were those of the jaws. There was considerable muscular atrophy. The head was fixed to one side and forward. Fig. 2, Case H, shows general conditions. Pains in connection with the joints were paroxysmal and severe. The rheumatism began sixteen years before and had been constantly progressive. This patient, when first seen by me, five months ago, had been a patient on the medical side of the City Hospital for three years. There was a history of gonorrhea when a young man, but of no subsequent trouble. In this case there was a marked sclerous seminal vesiculitis. Seminal vesiculotomy was performed four months ago. Five days after that operation, a condition of strangulated hemorrhoids developed which required operation. This hemorrhoidal operation unfortunately disturbed the drainage tubes in connection with the seminal vesiculotomy, so that they were prematurely forced out. I feared that the wound in connection with the seminal vesicles would consequently heal prematurely, before sufficient time for drainage had elapsed. There was a rapid improvement in rheumatic conditions. Six weeks after operation the patient could feed himself, and considerable movement had returned in his joints. Now, four months after operation, there is some return of the muscular pains and some restiffening of the joints, though he can still feed

Fig. 3.—Case I. From a photograph by Dr. H. H. Janeway.

himself. The wound closed prematurely, as I had feared. If the present relapsing conditions are not temporary, I propose to open the track of the wound for more and sufficient drainage.

Case I.—Man, 36 years of age. This case was of especial interest. The man entered the hospital on a

stretcher, running at the time a rather high fever. There was swelling of both hands and forearms, and both legs to well above the knees were swollen. These swollen areas, besides being edematous, were red, infiltrated, and very tender to the touch. Any movement of the parts caused so much pain that none was attempted. The trunk was marked with a late secondary syphilitic eruption, many of the lesions being rupial in character, indicative of a severe form of infection. There was also an urethral discharge containing gonococci. The clinical history was that four months, or thereabouts, previously gonorrhea and a chancre appeared at or about the same time. A month or so ago the systemic symptoms already described commenced, and quickly increased in severity. Two full intravenous injections of salvarsan were administered without apparently any special relief except as regards the eruption. Then, as the Wassermann reaction was still strongly positive, three more full injections of salvarsan were given at ten-day intervals. The fever gradually disappeared. The blood count showed only a slight degree of leucocytosis. The Wassermann reaction was negative after the five salvarsan injections. The gonorrheal fixation test, however, was very positive. For a time after the salvarsan there was some renal congestion and some puffiness of the face. After a few weeks the renal condition became normal. Although edema had disappeared from the extremities, still the rheumatic condition of the hands, wrists, and knees remained very active, as seen in Fig. 3, Case I, which was taken at this time. To account for the rheumatic condition a marked seminal vesiculitis existed. These organs were embedded in an inflammatory exudate, which was extensive enough to fill the post-prostatic cellular space. After the salvarsan treatment the patient was observed for two months, during which time there was no improvement. His heart action and general condition seemed too feeble to make a seminal vesiculotomy warranted. Finally, however, at the urgent request of the patient the operation was performed. He withstood the procedure without any undue reaction. The improvement after the seminal vesicles were drained was very rapid. Patient left the hospital well and active six weeks after operation.

The above results, which are only a few of many, give an idea of the wide field of usefulness which seminal vesiculotomy opens in the relief of rheumatic complications; and when one considers that there are numerous other resulting groups of symptoms which the operation in like manner relieves, it is not difficult to estimate its great value.

THE SCOPE OF RADIOGRAPHIC METHODS, FROM A CLINICAL VIEWPOINT, WITH SOME ILLUSTRATIVE CASES.

By LUCIUS A. WING, M.D.,

NEW YORK,

FELLOW IN MEDICINE AND CLINICAL INSTRUCTOR IN SURGERY, CORNELL UNIVERSITY MEDICAL COLLEGE IN NEW YORK CITY.

Radiographic methods have at present a wide spread field of usefulness as an aid in diagnosis. On account of the constant advance both in technique and in skill in interpretation, the possibilities and also the limits of usefulness of radiographic methods are still rather difficult to state definitely. From the clinician's viewpoint, the chief interest lies in the positive results obtained in diagnosis, and in their application. The writer's observations are based chiefly on experiences in Cornell University Medical College, Medical Clinic, where opportunity has been given him to gauge the relative importance of radiographic data in over 600 consecutive cases, covering a considerable variety. These cases were used largely for teaching purposes and had been carefully observed clinically.

Without going into an elaborate discussion as to the relative importance of the radiographic data in certain types of cases, the writer feels that the *x*-ray is almost indispensable in a thorough examination of the following types of cases.

1. *Fractures.*—The advent of the *x*-ray has shown us the great difficulty of an exact diagnosis in certain groups of fractures, particularly those in the region of, or involving joints, as there are so

Fig. 1.—Patient C. H. The lesion is indicated by the arrows.

many atypical varieties. All fractures should have a radiographic examination. Doubtful cases should be radiographed without a dressing; positive cases,

Fig. 2.—Patient J. P. An oblique radiograph of the thorax; the outline of the aneurysm is indicated by the arrows

after the adjustment and dressing are completed, to verify the correctness of the position.

2. *Types of Arthritis.*—The clinical evidence is of greater value in most cases than that afforded by the *x*-ray, unless the joint disease is secondary to

bone involvement. As an example, in early tuberculous disease of the hip joint; in cases where the epiphyseal involvement is the chief feature, the *x*-ray may give positive evidence while the clinical symptoms are still uncertain. If the synovia is

FIG. 3.—Patient J. I. Postero-anterior view of the aneurysm; the outlines of the aneurysm are indicated by the arrows. There is also a tuberculous involvement of the right apex, with a cavity (c).

chiefly involved, the symptoms are usually quite definite, and the radiograph will show very little.

3. *Diseases of Bone in General.*—A radiograph will show the location and extent of a bone lesion. It is diagnostic in sarcoma, syphilis, and subperiosteal hemorrhage. Anomalies and deformities are usually well shown. In all other bone lesions, the clinical evidence must be carefully considered, and one should not be tempted to make too positive a diagnosis on the radiograph alone.

Figure 1 is from a radiograph which shows the typical appearance of an early luetic periostitis, involving the lower third of the shaft of the humerus. This patient, C. H., age 40, a sailor, gave a history of a recent fall in which he bruised the arm rather severely. A few days later he noticed a tender swelling in the inner and posterior aspect of the arm about four inches above the elbow. This increased somewhat in size during the following ten days, and was accompanied by dull aching pain in the whole arm. After seeing the radiograph, close questioning brought out an indefinite luetic history. The Wassermann was strongly positive. The local condition disappeared promptly under treatment.

4. *Foreign Bodies in the Tissues.*—Stereoscopic and angulation methods have made the localization of foreign bodies more accurate. If deeply embedded, they are frequently difficult to find at operation, even with the best of radiographs as an aid. Some foreign bodies do not show on an *x*-ray plate; in case of doubt, a body similar to that suspected may be tested by radiographing it through an equivalent amount of tissue.

5. *Calculi in the Kidney, Ureter, and Bladder.*—Any stone of sufficient size to warrant surgical procedure, should show in a radiograph with good technique, with the occasional exception of a small soft calculus in front of the sacrum, or just above the brim of the pelvis. A positive diagnosis of calculi should always be confirmed by repeating the plates, to rule out an artifact. Special methods of examining the tract by means of radiographs taken after the passage of instruments, or after the injection of certain solutions, are sometimes valuable. Since the advent of dependable radiographic methods, it would appear that calculi are more frequent than was formerly supposed. The symptoms are often indefinite or misleading. The *x*-ray is our most valuable aid in deciding these cases.

6. *Pulmonary Cases.*—In the diagnosis of pulmonary tuberculosis, particularly in early cases and in cases where the involvement is chiefly about the root of the lung, good radiographs are of great value. They are also of value in more advanced cases in following the progress of the lesion. In pleurisy with effusion, and in empyema, the clinical symptoms and signs and the needle are usually quite sufficient for the diagnosis. There are cases, however, where the fluid collection is small in amount and localized, and the needle may fail to show it. These small collections show readily in a radiograph. On account of the permeability of the chest wall to the *x*-ray, foreign bodies, even of soft density, will show. In lung abscess, the location and size of the lesion are readily observed in a radiograph.

7. *Aneurysm, and Dilatation of the Arch of the Aorta.*—Radiographs are indispensable in making an early diagnosis in these cases. Aneurysms may attain considerable size without giving positive signs, and it is a matter of common observation that a majority of these cases are well advanced before a diagnosis is made on clinical evidence alone.

The following case illustrates the value of a radiograph in a doubtful case:

J. P., age 56, colored, porter. This patient gave a history of chronic cough lasting several years. He was found to have pulmonary tuberculosis in a rather advanced stage. The cough was persistent and loose, the sputum abundant and contained many tubercle bacilli. Arteriosclerosis was fairly marked, and the heart enlarged. The area of cardiac dullness extended upwards as well as in other directions, no murmurs were heard. There were varicosities of considerable size in both legs, and varicosities extending upwards over the abdominal wall to a rather marked degree.

Pulmonary tuberculosis was at first believed to be the chief condition present, and the extension of the area of

cardiac dullness upwards, and the evidence of mediastinal pressure on the venous trunks were both thought due to tuberculous involvement of the mediastinum. The large aneurysm of the arch, the clinical evidences of which were pretty completely masked by the pulmonary condi-

Fig. 4.—Patient H. P. Above the arrows, the lumen of the esophagus is shown dilated by the bismuth; below, the area of encroachment on the lumen of the esophagus is indicated by the defective bismuth outline, showing the area involved with carcinoma (c).

tion, caused the patient's death about three months later. (See figures 2 and 3.)

8. *Lesions of the Esophagus.*—Clinical evidence, obtained by special examination and instrumentation, is supplemented and confirmed by radiographic examination. In doubtful cases, the latter is frequently diagnostic. The x-ray is of great assistance in the study and differentiation of the following conditions: Spasm of the esophagus, stricture, either benign or malignant, and diverticulum.

The accompanying illustration shows the typical appearance of a fairly advanced case of carcinoma of the esophagus, the clinical history of which was kindly given by Dr. Morris Zucker, as follows:

Mrs. H. P., Russian, age 50, married, 7 children. 1 miscarriage. Father died of old age. Mother of cancer of the stomach. The patient has had bronchial asthma for the past 20 years. She has never had any gastric symptoms nor constipation. About six months ago she began to complain of peculiar uneasy burning choking pain in the chest, referred particularly behind the ensiform cartilage. This developed into sharp burning pain during the swallowing of solids. Later she complained of difficulty in swallowing solids. At this time a stomach tube passed easily, but with a peculiar grasp on withdrawal, giving the sensation of cardiospasm. (This was the diagnosis made at this time by a well-known internist.) A gastric analysis made a little later showed blood cells present, total acidity increased, undigested starch granules. Radiographs made at this time (Fig. 4) during the passage of bismuth through the esophagus, enabled a positive diagnosis of carcinoma to be made. Up to this time the patient had lost very little weight or strength. The subsequent course of the case confirmed the diagnosis. There was no operation.

9. *Conditions Involving the Colon.*—Two methods of investigating the colon radiographically are of value: (1) To follow the food through with bismuth, to determine the motor efficiency of the colon. (2) By bismuth enemas to determine the size, shape, and position of the colon and the condition of the lumen with reference to the presence of strictures or new growths. A positive or negative diagnosis of organic obstruction can be made in this way, and usually the type of obstruction. In any case, the surgical indications can be determined more definitely. It appears to the writer that too much stress has been laid on the so called prolapse and angulation of the colon as a pathological condition, as the same anatomical condition appears frequently in healthy individuals. If bismuth passes through the colon within 36 hours, there should be great hesitation in considering the function abnormal, regardless of the anatomical position.

10. *Gastric Cases.*—The investigation of various gastric conditions is a field in which radiography is proving increasingly valuable, and particularly so when the methods are applied in close cooperation with the other clinical methods and the data obtained thereby. A few plates made after the ingestion of bismuth are sufficient to show the size, shape, position, and evacuation time of the stomach.

A series of plates will give in a great majority of cases, a positive or negative diagnosis of early carcinoma, or of indurated ulcer of the stomach or duodenum, and will also give valuable evidence in certain other lesions, which may or may not require surgical procedure; among these are spasm of the pylorus and types of adhesions, with or without obstruction. Doubtful gastric cases in which there is a possibility of early carcinoma, should certainly be investigated radiographically, the only alternative being an early exploratory operation.

The following two carcinoma cases, of different types clinically, illustrate some of the difficulties which may be met in making a diagnosis early in these cases, and the aid which can be given by radiography.

Case I.—Chronic gastric ulcer, hour glass contraction, carcinomatous change at the base of the ulcer. A. J., age 42, watchman, born in Scotland. Family history negative. Past history: heavy drinker of whiskey; venereal history negative; chronic cough for the past 12 years. Six years ago had the entire left shoulder girdle removed by Dr. John Douglas, for sarcoma of the humerus. Present history:

Fig. 5.—Patient A. J. C., area of constriction of the hour-glass stomach; U. P., upper pole overdistended with bismuth meal; L. P. lower pole defectively filled with bismuth meal, due to the small caliber of the stenosed portion.

desultory attendant at the clinic for the past 18 months, during this time he frequently drank heavily. During the past 5 months he has had a good deal of epigastric distress and dull pain, and has taken much less alcohol during this time. There have been occasional attacks of nausea

and vomiting, which have recently become more frequent. He has not noticed any blood in the vomitus. There has been a loss of 10 pounds in weight in the past 5 months, and considerable loss in strength. The appetite has become poor, and the bowels constipated, and at present the dull epigastric pain is very persistent, and apparently made worse by taking solid food. Physical examination shows a rather poorly nourished man, 5 feet 9 inches tall, and weighing 141 pounds; skin and mucous membranes are pale. The entire left shoulder girdle has been removed, there are no local evidences of any recurrence of the original tumor. Lungs show signs of a chronic bronchitis. Heart is normal. Abdomen is thin walled and flat. Liver and spleen are not palpable. There is tenderness and some rigidity on pressure in the epigastric region. No masses can be felt. Blood examination shows red cells, 4,040,000; hemoglobin, 55 per cent.; white cells, 13,000; polynuclears, 79 per cent. Urine showed a faint trace of albumin, otherwise was negative. Sputum was abundant, mucopurulent, tubercle bacilli not found. Gastric analysis was not made, as the patient objected. Radiographs were made after a bismuth meal. These were believed to show evidence of an hour-glass contraction of the stomach (Fig. 5); probably due to chronic ulcer, with extensive adhesions involving the lower segment. Operation was advised. A few days later the patient consulted Dr. John Douglas, who operated, and kindly gave me his findings, as follows: Extensive adhesions were found between the posterior surface of the lower segment of the stomach and the pancreas

Fig. 6.—Patient M. M. The defect in the filling outline of the stomach is due to encroachment on the lumen by a carcinoma of the greater curvature. The outline of the carcinoma (c) is indicated by the dotted line.

and adjacent structures. A large callous ulcer was present in the posterior wall of the stomach at the site of the adhesions, the tissue was very friable and necessitated an attempt at removal. A partial gastrectomy was done. Sections made from the area of the ulcer were reported by Professor Ewing as showing early carcinomatous change at the base of the ulcer.

Case II.—A gastric carcinoma of considerable size, producing very slight gastric symptoms. M. M., age 56, clerk, born in Germany. Family history good. Past history: total abstainer, regular habits, no venereal history. Excellent health until 9 months ago. Present history: for the past 9 months has had attacks of giddiness which have been increasing in frequency, and this has caused him to consult a physician. His appetite is fairly good, though not as good as formerly, and he frequently belches gas after eating, and has a slight feeling of weight in the epigastrium. The bowels are regular. He has lost a little weight. Physical examination: the man's pallor is rather striking, though his nutrition is good. Palpable arteries are moderately thickened. The heart and lungs are practically normal for a man of his age. Abdomen: walls fairly thick, soft, no tenderness, no masses. Liver and spleen, not palpable. Blood examination shows red cells, 3,800,000; hemoglobin, 65 per cent.; white cells, 8,000; polynuclears, 70 per cent. Urine showed a very faint trace of albumin, no casts; examination otherwise negative. Gastric analysis showed: Free HCl—0. Combined HCl—0. Total acid, 12. Occult blood, negative. Radiographs of the stomach were made after a bismuth meal, and showed a typical shadow of a gastric carcinoma of the greater curvature, towards the pyloric end (Fig. 6). The pylorus was apparently not involved, and the growth was not ulcerating, which seemed to explain the absence of more severe gastric symptoms. The patient declined operation, and was eventually lost sight of.

There are certain other types of cases in which radiography is of value, but these belong rather closely to various specialties, and do not fall within the scope of general diagnosis, and will not be discussed.

Conclusions.—The *x*-ray should not be regarded as something apart from other methods of physical examination, but as a supplemental method, and often a very valuable one.

It should be employed more frequently, and clinicians in general should be more familiar with its scope of usefulness, including its limitations.

It is very desirable that the radiographer and the clinician be in close relation in the matter of radiographic interpretation, so that the entire evidence in a given case can be weighed in a consistent manner.

The writer is indebted to Dr. Lewis G. Cole and Dr. Arthur F. Holding for the plates shown in these cases.

375 Park Avenue.

SYRINGOMYELIA; WITH PATHOLOGICAL FINDINGS*

By E. P. Bernstein, M.D.,

and

S. Horwitt, M.D.

New York.

Syringomyelia in its literal meaning signifies a tubulation of the spinal cord. As such this lesion was described as early as the middle of the 16th century. As a clinical entity, however, it was not recognized and studied until the middle of the 19th century when Kahler and Schlutze presented their classical paper on this subject. This pioneer work gave an impetus to a host of celebrated neurologists and pathologists and resulted in a wealth of literature.

From a critical study of numerous cases it was found that cavitation of the spinal cord may arise in diverse ways. Thus in a number of cases the tubulation is of congenital origin, being due to a failure of union of the walls of the primitive neural groove and the neural canal posteriorly. In its most pronounced form this condition gives rise to what is known as a myelocele which protrudes above the level of the skin through a spina bifida. In such cases, as might be expected, the cavity is lined with apendyma cells throughout its entire extent. Again it is possible for a dilatation of the central canal to be acquired through some disorder of the flow of cerebrospinal fluid. In these cases too, the cavity is lined with apendyma cells, and a process of gliosis in the neighborhood is absent. These conditions are not included in the class of syringomyelias. They are termed hydromyelias. Aside from dilatations of the spinal canal, cavities may also arise by a process of softening and absorption following a thrombosis of the supplying artery, or a traumatic hemorrhage (hematomyelia), or inflammatory destruction of tissue. These conditions, however, are not true syringomyelias. By syringomyelia in the strict sense of the word we now understand a progressive pathological process result-

*From the Pathological Laboratory of Lebanon Hospital.

ing in cavity formation in the substance of the cord, usually occurring in the gray commissure and associated with a gliosis or proliferation of glia tissue. It is commonly accepted that the gliosis is the primary lesion occurring as a new growth, and that as

Fig. 1.—Section of cauda equina, glioma. *gd*, Gland-like cavity, lined by apendyma cells *ep*; *bl*, extravasated blood; *ph*, phagocytic cells laden with pigment derived from area *bl*. These cells can be followed up into the lymph spaces of the connective tissue *ct*, which is seen to invade and replace the tumor parenchyma.

a result of degeneration of the tumor tissue cavities are formed.

Clinically the disease may present an immense variety of symptoms, which for convenience we may arrange in the following groups:

1. Motor Disorders: muscular atrophy, paresis, rigidity, increased tendon reflexes.

2. Sensory Disturbances: manifesting themselves by a dissociation of sensation, that is, a loss of pain and temperature sense with preservation of the tactile and deep muscular sense.

3. Trophic Disorders: panaritium swellings, bullæ formations, anomalies of sweat excretion, spontaneous bone fractures, arthropathies, kyphoscoliosis, chiromegaly.

4. Should the process involve the medulla we may get bulbar symptoms as hemiatrophy of the tongue, recurrens paralysis, nystagmus.

As any combination of the above symptoms may exist, the disease may give quite dissimilar clinical pictures, thus:

1. Motor symptoms predominating, the case would resemble spastic spinal paraplegia or amyotrophic lateral sclerosis.

2. With sensory symptoms most prominent, the case may simulate leprosy.

3. A tabetic type of the disease.

4. The disease may resemble pachymeningitis.

5. Finally, the classical cases with involvement of the upper extremities, wasting of the interossei, and dissociation of sensation of the upper extremities, as described above.

This diversity of symptoms will not be wondered at when it is remembered that the cavity may vary in its situation, level, extent, and configuration and also that there may be a number of cavities present.

When single, the lesion most commonly involves the cervical enlargement, though it may be found in any part of the cord and even in the medulla.

As a rule the disease arises in the posterior commissure, behind the central canal and usually involves the anterior parts of the posterior columns and posterior grey horns.

The cavity may be so small as to give rise to but few symptoms. It may on the other hand, by extension, compress or destroy the posterior columns, posterior grey horns and even the crossed pyramidal tracts. Then again the cavity may be of various shapes with irregular extension in various directions, thus giving rise to most irregular symptom complexes.

With regard to the association of the cavities with gliosis, some observers are inclined to consider the gliosis a secondary process, a sort of inflammatory reaction peculiar to some disease of the cord. Thus it is found that in tumors of the cord a cavity may be found at, above, or below the level of the tumor (Schlesinger). Still such association is not constant as would have to be the case if gliosis is a reaction process of glia tissue to abnormal conditions. On the other hand, the view in accord with the greatest number of observations and the one accepted by most observers of today is that the gliosis is the primary process and that cavitation is a result of degeneration occurring in the glia neoplasm—a sequel not uncommon in other tumors.

This theory further assumes that in the process of closing in of the posterior part of the neural canal during embryonal life some primitive cells or nests of cells (spongioblasts or neuroblasts) endowed with the capacity of proliferation were included and preserved. These embryonal cells may lie dormant for many years and then, whatever the determining stimulus may be, resume their property of proliferation. This theory of the origin of this lesion will further account for its location at or behind the central canal. For it will be recalled that the central canal represents but the anterior portion of the primitive neural canal.

With these preliminary remarks on the present status of syringomyelia, we are ready to analyze the following case:

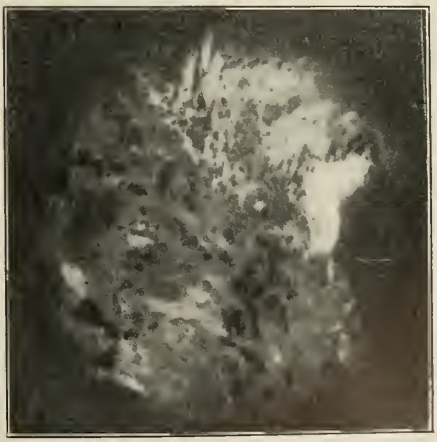

Fig. 2.—High power of area *ph*, in Fig. 1.

R. M., female, 49 years of age, admitted to the Lebanon Hospital, service of Dr. Leszynsky, February 23, 1912. Previous history, negative. Present history began nine years before admission with attacks of pain over sacrum and left leg. Attacks gradually became more frequent.

Then both legs became involved. On admission, root pains over both legs and sacrum, both extremities helpless, flaccid paralysis; anesthesia; areas of dissociated sensation; extensive bedsores, with deep ulcers over both buttocks. Died from toxemia and exhaustion, March 19, 1912.

FIG. 3.—Section from cauda equina glioma, showing adenomatous character. *c*, Gland-like cavity; *s*, secretion; *ep*, ependymal lining, columnar cells; *gl*, polyhedral glia cells.

Autopsy, March 19, 1912. (Unfortunately permission for only a spinal cord incision was obtainable.) Vertebral column showed a right lumbar scoliosis.

Spinal Canal.—From tenth dorsal vertebra down, the spinal canal shows considerable dilatation. Bony and ligamentous structures look healthy. Dura externally shows no exudates, adhesions, or thickenings; internally, dura becomes adherent to inclosed structures at the level of the conus (first lumbar vertebra).

Cord.—Marked increase in diameter of lumbar enlargement. Looks distended. On transverse section this is found to be the site of a longitudinal cavity of irregular shape, differing at different levels. The lower part of the lumbar enlargement shows an extensive cavity to the left of the median line, behind the site of the central canal. To the right of the median line is an area of dense whitish tissue occupying the columns of Goll and Burdach. In the right anterior portion of this whitish area is a small cavity. In the upper part of the lumbar enlargement the cavity is more symmetrical, being oval in shape, occupies the region of the posterior commissure and the anterior portions of the columns of Goll and Burdach, and the anterior portion of the posterior horns. At each lateral wall of the cavity is a rim of dense whitish tissue. A section in the cervical enlargement shows a small cavity, to the right of the middle line. A little lower down another small cavity to the left of the middle line. While at a still lower level the two are seen to unite by a narrow strait. Then the site of the cavity is seen to be filled with a brittle yellowish material sharply sequestrated from the surrounding cord tissue.

Cauda Equina.—The interior of the dural sheath is here occupied by tumor tissue, which in the upper part is of a fibrohyaline consistency, including some nerve fibers of the cauda equina in its substance, and crowding others peripherally. The lowermost portion of the dural sheath, at its sacral termination, is occupied by a mass the size of a pigeon's egg, reddish grey, mottled, granular, and friable. The nerves are coursing between it and the dura.

Microscopical Findings.—The portion occupying the lowermost parts of the dural sheath presents three chief histological elements—cellular tissue, fibrous connective tissue, and hyaline masses. The cellular tissue is found to be made up of cell units of the nature of young glia cells. Their nuclei are large and vesicular. Some nuclei are unusually large. The rim of protoplasm appears larger than in the mature glia cells. Glia fibers are scant, and there is no evidence of a glia reticulum, such as is seen in the areas of gliosis, in the neighborhood of the syringomyelia cavities to be presently described. The conglomerations of cells are penetrated and invaded by strands of connective tissue. In some areas the fibrous tissue seems to spring from the blood vessels. The walls of the latter are thickened and hyaline. In other parts the glia cells are differentiated into ependymal cells which line gland-like cavities (neuroepithelioma adenomatosum gliomatosum). Intercellular extravasation of blood is only occasionally seen. But there are numerous areas of hyaline or slightly fibrillar structure which represents masses of blood and fibrin changed beyond recognition. The fibrous tissue bundles are seen to be invaded by wandering cells which are heavily laden with blood pigment from the extravasates. Sections from the cauda equina, where the tumor appears in the gross as fibrohyaline, show microscopically a dense fibrous tissue structure with here and there a pigment-bearing phagocyte, but with no neural elements at all. (Figs. 1, 2, and 3.)

The lumbar enlargement in its lower part shows in some sections the central canal with an ependymal lining completely preserved. In the immediate neighborhood of the latter, posteriorly, is to be seen a collection of large glia cells, with comparatively little intercellular fibrils, resembling the cellular tissue seen in the gliomatous tumor at the lower extremity of the cauda described above. Other sections fail to show the lumen of the central canal, but the area of glia proliferation is present. (Fig. 5.) In either case, behind the collection of these young glia cells is situated an area of gliosis, consisting of a dense reticulum of glia fibers with an increased number of mature glia cells possessing a dark staining nucleus with a very thin protoplasmic rim. The mass of gliosis occupies the anterior half of the left columns of Goll and Burdach. At the left and anterior angle of this mass is a small cavity encroaching slightly on the adjacent portion of the posterior horn. On the right side there is a large cavity with but a small area of gliosis bordering it. The glia masses are not sharply delimited from the surrounding tissue. The blood-vessels in their neighborhood show hyaline changes and thickening. The cavities are nowhere lined by ependyma or any other cells. The anterior horns are distorted. The posterior horns are largely destroyed. The nerves cut at this level show increase of perineural fibrous tissue. (Fig. 4.)

In the upper lumbar region there is a large single cavity, of oval shape, the longer diameter being transverse. It occupies the region behind the posterior commissure and involves the posterior columns and the posterior horns. Here, too, a central canal with a neighboring area of glia cell proliferation is found. Each lateral boundary

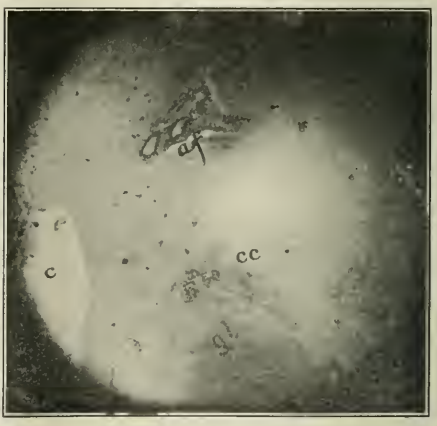

FIG. 4.—Section middle lumbar region. *af*, bottom of anterior fissure, showing blood vessels; *cc*, central canal surrounded by area of proliferation of fia cells; *gl*, area of gliosis—dense texture of glia fibers with few cells; *c*, cavitation.

shows a dense texture of glia tissue, the cells being small and the intercellular fibers predominating. (Fig. 6.)

In the cervical region areas of gliosis have not been found. An irregular cavity was found at one level, consisting of two lateral parts joined by a narrow transverse

strait. Examination of serial sections showed how this strait gradually grew narrower and finally disappeared, leaving two separate cavities, one on each side of the middle line. These cavities also grew smaller and finally disappeared. The erstwhile central canal is indicated on

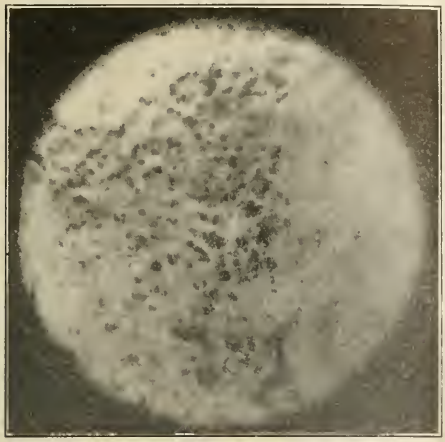

Fig. 5.—High power of area (c.c) in Fig. 4.

the posterior border of the right side cavity where it is lined over a small portion of its extent by ependymal cells. Here again there is a proliferation area of glia cells behind the ependymal rim. In sections where neither a cavity nor an area of gliosis was found there was still found proliferation of glia cells in the immediate neighborhood of the central canal.

To sum up, the cavities found at all levels of the cord were not dilatations of the central canal. In every instance, however, they were situated close to it. In the lumbar region, where the central canal is in part preserved, the cavities and islands of gliosis are seen to be located behind and in close proximity to it. And while the areas of gliosis are composed of small glia cells, with a thin rim of protoplasm, the region immediately sur-

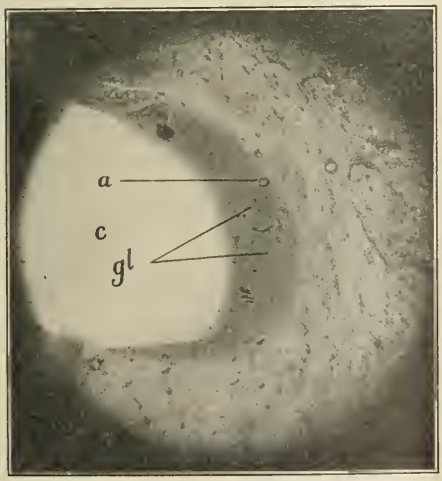

Fig. 6.—Upper lumbar region. *c*, cavitation—no ependymal lining; *gl*, rim of gliosis surrounding cavity; *a*, artery—note hyaline degeneration of walls.

rounding the ependymal cells is seen to contain younger, less differentiated glia cells, with larger nuclei and wider protoplasmic rims. In the cervical region, no areas of gliosis, such as were found in the lumbar sections, were seen. Cavities are here found in segments. The cavities are seen at some levels to have broken into the spinal canal, which explains their partial ependymal lining. Here again, close to the ependyma cells is seen an area of prolifeated young glia cells. Some of the cells contain large vesicular nuclei and brush-like processes at two poles, thus resembling in form the spongioblasts of the embryonal cord. In the cervical region also there is seen a stage preliminary to cavity formation in which the cells in the affected area are distended, polygonal, hydropic, and on the road to disintegration. The cauda equina is occupied in its upper part by fibrous tissue, while the lower part consists of a gliomatous neoplasm, where the glia cells are of the young undifferentiated type, with glia fibers and processes but little developed (glioma molle). Some of the glia cells, however, are differentiated into columnar ependyma, similar to the cells which line gland-like cavities. The tumor is seen to be invaded by fibrous tissue strands.

The blood-vessels are generally found to have thickened walls and show various grades of hyaline degeneration.

Conclusion.—The pathological findings just enumerated appear at first sight dissimilar. The disparity however does not concern the essential underlying principle of the origin of the lesion. The origin of all the diverse lesions seem to lie in neoplastic proliferation of glia cells. In the cauda equina this proliferation has resulted in a gliomatous tumor mass. Here it is in part invaded by fibrous tissue and extravasations. In the upper part of the cauda equina tumor there was originally in all likelihood a gliomatous tumor which in time has been entirely replaced by fibrous tissue growing from the dural coating. Within the spinal cord proper, there is cell proliferation close to the central canal. In the lumbar region there are seen areas of gliosis which perhaps may bear towards the tissue we called glioma a relation similar to that which a fibroma bears towards sarcoma (leaving out of consideration the question of malignancy). In the cervical region there is proliferation of glia cells close to the ependymal cells. Cavities are found at some levels and none at others. Whether the cavities resulted from callequefaction of a gliomatous area or whether it arose in some other way as a response to the pathological proliferation of cells close to the central canal would be hard to say. Another disparity in the end results of the cauda tumor and the lesions in the cord proper is that in the one the neural tissue after destruction is replaced by fibrous tissue, while in the other no such attempt is seen. To explain this difference it should be remembered that there is too little fibrous tissue found in the cord substance to serve as a starting point for scar formation. Pathological defects in the brain, as for instance non fatal hemorrhage, usually results in cyst-like cavities and not, as in other organs, in scars.

A HITHERTO UNDESCRIBED FORM OF POLYCYTHEMIA AND ITS POSSIBLE RELATION TO DUODENAL ULCER, CHRONIC PANCREATITIS, AND A DISTURBANCE OF INTERNAL SECRETIONS (ADRENALIN).*

By G. A. FRIEDMAN, M.D.,

NEW YORK,

ATTENDING PHYSICIAN IN DIGESTIVE DISEASES, VANDERBILT CLINIC.

Polycythemia, polyglobulia, erythremia, erythrocytosis, are the usual terms for an increased number of red blood corpuscles. The two latter terms were fittingly chosen in analogy with leucemia

*Read at the Section of Medicine, New York Academy of Medicine, April 15, 1913.

and leucocytosis. If the number of red cells exceed five and one-half millions in a cubic centimeter of blood, the condition of polyglobulia can be spoken of. (Aubertin.)[1] A marked increase in erythrocytes may occur physiologically in new-born children[2] and in adults who are living in high altitudes. Pathologically it occurs in starvation and in losses of fluid from the body as from persistent vomiting, profuse sweating, severe diarrheas. Cholera Asiatica may serve as the best instance of the occurrence of polyglobulia, due to losses of body fluid. A numerical increase of red blood corpuscles occurs in congenital and acquired heart disease with disturbed compensation, in emphysema and in edema of the lungs.

Poisoning with phosphorus, arsenic, carbon oxide may also lead to the condition of polyglobulia. The latter toxic form of polyglobulia has been named, acording to Parkes Weber,[3] anemic polyglobulia, "la polyglobulie anémique," as the percentage of hemoglobin is too low in comparison with the high counts of red cells. Further should be mentioned the occurrence of polyglobulia in gastrosuccorrhea and patients with reduced intake of fluid, as occasionally in chronic constipation.

In 1892 first Vaquez,[4] later Turck,[4] Osler,[4] and others described a form of true polycythemia occurring in middle-aged people, the so-called Vaquez or Vaquez-Osler's disease, chiefly characterized by splenomegaly, associated with cyanosis of the face. The hemoglobin in this disease is rather in disproportion to the numerical increase of erythrocytes. The autopsy in such cases revealed a true plethora, since all parts of the body seem to contain large quantities of blood. In three such instances primary tuberculosis of the spleen was found.

It should be added that the causes of most polycythemias remain obscure. Those forms of polyglobulia, which occur in people after severe losses of body fluid, seems to be explained more satisfactorily than others. Thickening or concentration of the blood in such individuals was said to be responsible for high counts of red blood corpuscles. In disease of the heart, in emphysema of the lungs, and in edema, stasis of the blood seems to be the cause. The high altitude hyperglobulism is probably compensatory to lack of oxygen in the air, and there is increased activity of the bone marrow (Osler[5]). In true erythremia this same increased activity of the bone marrow is present. Vaquez-Osler's disease is, therefore, considered as a primary lesion of the bone marrow, just as leucemia is an affection of the leucoblastic elements. But the immediate cause of the hyperactivity has not been yet established.

Our patients in whom the hemoglobin showed from 85 to 110 per cent. and counts of red blood corpuscles from six million to about eight million do not belong to any of the groups mentioned. They are not inhabitants of high altitudes, but are living in New York City. Nearly all of them had a very good appetite and therefore the polyglobulia was not due to starvation. No lack of thirst could be elicited from the histories; some even used water in large quantities. Severe diarrheas or sweating were not mentioned by any one of our patients. Those of them who vomited shortly before counts were made did not enter into our series of cases. Only two of the patients looked slightly cyanotic and one showed slight cyanosis of the lower lip. All others looked rather pale, or more correctly, dried out.

Our material consists of fourteen patients from private practice and eleven from the Vanderbilt Clinic. Twenty-three were males and two females. The ages ranged from 19 to 57 years. All of our twenty-five patients complained of the usual symptoms of chronic indigestion and of attacks of pain. The paroxysmal pain dated back mostly for years, and in a large number constant pain was also complained of. Many complained of night pain; some of hunger pain, others of both. A large number of them were users of bicarbonate of soda, which remedy they took at night on account of pain or on retiring in order to avoid night pain. Jaundice could not be elicited from a single history. Objectively there could be demonstrated in all our cases tenderness of different intensity to right of the epigastrium, in the continuation of right parasternal line somewhat above the navel; in but a few instances tenderness was found also somewhat to left of navel, and in one patient there was also tenderness in the appendicular region. In none of the patients was either liver border palpable, or spleen enlarged, or gallbladder palpable. There were no tender spots characteristic for gallstone disease or for gastric ulcer.

Gastric analysis: With the exception of four cases, in which stagnation of food was found on fasting stomach and in one case with intermittent stagnation, there was no macro- nor microscopical stasis on fasting in all the rest. The amount obtained on fasting stomach ranged from nothing in one case to 20-30-90 in others. After test breakfast amounts much over normal were obtained, and the volume of fluid was 2-3-4-5 times larger than the volume of solids. In but one instance, in which at the operation gastric and duodenal ulcer was found, the volume of solids was equal to the volume of fluids. Hyperacidity was noted in all, except for one case of hypoacidity and for another of heterochylia.

Feces: The presence of occult blood could be demonstrated with the guaiac test only in a small number of cases, though with benzidin more frequently. A complete analysis of the feces of three patients showed pancreatic insufficiency. One of these cases came to autopsy and was proven to be chronic interstitial pancreatitis. Urine was negative, except for a large sediment of phosphates in some and transient glycosuria in two.

In order to avoid repetitions two tables are added:

Case I.—R. S., aged 37, merchant. Was seen first August 6, 1911. Ailing for ten years with indigestion and attacks of cutting pain in the upper abdomen from four to six hours after meals. For last few years he is suffering also with constant pain during day and at night. Appetite has been always very good. He drinks from six to eight glasses of water daily. Several years ago had noticed on two occasions that his stools were black. Never vomited. His illness was diagnosed by some physicians as gastric, by others as duodenal ulcer. Examination: Marked tenderness in upper quadrant of the abdomen to right and slight rigidity of rectus muscle in this region. Guaiac test for occult blood in the feces twice negative, once positive. Polyglobulia was found on two occasions.

Case II.—B-r, H., aged 47, merchant. Seen first July 28, 1912. Attacks of abdominal cramps with long intermissions of good health since twenty years. Patient has frequently pain in the abdomen at night, for which he is compelled to take bicarbonate of soda. Lately pain comes on also at other times and he feels relieved only after taking some nourishment. He was never jaundiced. Examination: Looks "dried out." Great tenderness above the navel to right, no tender spots anywhere else. Occult blood in the feces negative on three examinations. Polyglobulia on three examinations. In September 1 was called to his house on account of a severe attack of abdominal pain. I found at that examination his right

rectus muscle very rigid. Operation for duodenal ulcer was advised. Later, I have heard, he visited a physician who treated him for dyspepsia. I have been informed by a friend that he had a severe attack in December.

Case III.—N-l, Max, 38, painter. Seen October 25, 1911. Patient has been suffering for fifteen years with intense paroxysmal pain at the lower third of the sternum. The attacks became more frequent for last two years. The pain is of burning character, at times has no relation to food, at others he is relieved by food. Vomited on several occasions during the course of his illness, but not lately. He also had night pain. Appetite is capricious. Lost lately six pounds in weight. Obstinate constipation. Had on several occasions tarry movements (without medication). Past illness: Smallpox in childhood, typhoid fever 16 years ago. Examination: Great tenderness in right parasternal line at the navel. Occult blood negative on three examinations. Polyglobulia on one examination. Report of *x*-ray plates, made by Dr. L. G. Cole (October 29, 1912). From a study of the plates there is definite evidence of a lesion involving the extreme pyloric end of the stomach with partial obstruction.

Case IV.—H-t, S., aged 24, tailor. Seen September 2, 1912. Two years ago, shortly after typhoid fever, started to complain of indigestion. For one year he has had attacks of burning pain in lower abdomen (mostly at night). Examination: Appears "dried out." Great tenderness in appendicular region. Guaiac test negative on three occasions, benzidin once positive. Polyglobulia on three occasions, oligoglobulia on one occasion. November first I was called to the patient's house on account of vomiting (first time in his illness), which occurred several times while at work. Examination revealed this time also tenderness at the right hypochondrium. Diagnosis: Chronic non-complicated duodenal ulcer. Operation: November 7 (Dr. A. Gerster). Appendix intact without ulcerations, round and firm band around the first part of duodenum and adhesions between gallbladder and duodenum. Gallstones were not found. Stomach was normal.

Case V.—C-n, R., aged 42, housewife. Seen October 7, 1912. Had had five years ago severe attacks of burning pain in the region of right hypochondrium. The pain did not radiate to the back or shoulders. For last two years she had heartburn and constant pain on fasting stomach. About 18 months ago she fainted on one occasion while moving her bowels. She was told that her stools looked like ink. Subsequently she had noticed on two occasions black motions. Patient had never vomited, nor was ever jaundiced. Her condition was diagnosed at that time, as gastric ulcer. Since last six weeks the pain was more severe than ever. Examination: Great tenderness about two fingers to right of umbilicus. Occult blood negative on three examinations. Polyglobulia found on three examinations.

Case VI.—W-f, J., aged 42, furrier. Seen first November 8, 1912. For many years has had attacks of abdominal pain. Sleep is frequently disturbed on account of pain, which comes on at midnight and during the day 5-6 hours after meals. Examination: Great tenderness somewhat above the navel to right, also at 12th rib, near the spine. Occult blood negative. Polyglobulia on two examinations.

Case VII.—B-l, B., aged 24, engineer, January 9, 1913. Ailing for 18 months with burning pain 2-4 hours after meals in right hypochondrium. Lately he has also pain at midnight, which he can avoid by taking bicarbonate of soda on retiring. Constipation. Examination: Looks somewhat plethoric. Great tenderness to right of epigastrium and somewhat above the navel, where the rectus muscle is rigid. Occult blood negative. Polyglobulia on one examination.

Case VIII.—J-s, A., aged 38, cigar store. Seen October 29, 1911. Attacks of abdominal pain and indigestion for nine years. Examination: Great tenderness at the navel to right. He was seen by me many times and about a dozen gastric analyses were made. The contents showed at times stagnation of food, at times no stagnation. This transient ectasia was probably due to pylorospasm, as I have seen it several times in patients with duodenal ulcer, which was proven at operation. Patient felt perfectly well for one year, when paroxysmal pain came on again. Occult blood twice positive, twice negative. Polyglobulia was found on two examinations. Patient

was advised to be operated upon for duodenal ulcer, but escaped from observation.

Case IX.—A-z, L., aged 33, tailor. Seen January 26, 1913. Patient is ailing for 15 months with indigestion and cutting pain in epigastric region from 5-6 hours after meals. He vomited many times at the beginning of his illness. Complains also of night pain and hunger pain. Examination: Tenderness in region of navel, more to left. Polyglobulia on two examinations.

Case X.—K-n, M., 23, traveling salesman. First seen November 9, 1912. Attacks of abdominal cramps for five years. Four years ago was operated upon for epigastric hernia, three years ago an abdominal incision was again made, but peritoneum was not opened at both operations. In May, 1911, a third laparotomy was performed, a healthy appendix removed and adhesions between colon and pylorus. A thorough exploration of the duodenum has not been made. Since three years has hunger pain, mostly at night, for which he drinks milk. He has intense pain in the abdomen after motions, especially when they are loose, as it often happens. Lately he has also spontaneous pain on walking. Pain relieved while sitting or bending his knees. Cold drinks and whiskey also relieve pain. Examination: Looks pale. Great tenderness in epigastric region and around the navel to right, otherwise negative. Occult blood twice positive. Dr. Oefele made a complete analysis of the feces and reported the case as plainly that of pancreatic insufficiency. Polyglobulia was found on three examinations. Diagnosis: Duodenal ulcer. March 10, 1913, operated by Dr. A. A. Berg. Adhesions between gallbladder and colon, firm adhesions between gallbladder and the duodenum. On the posterior wall of the duodenum a scar from a probable old ulcer of the mucous membrane. Pylorus tied. Posterior gastrojejunostomy.

Case XI.—B-e, I., aged 43, merchant. Seen first January 17, 1913. Ailing for ten years with indigestion. Attacks of *cramp-like pain,* of pinching character. For two years has been perfectly well. Lately he was sick six weeks and then again well. Pain is frequently relieved after food. Anorexia and constipation. Wakes up at night on account of pain and takes bicarbonate of soda. Pain radiates lately to the back. Examination: Tenderness in right axillary line and to left in region of colon descendens; slight rigidity of right rectus muscle. Clinical diagnosis: Gastic ulcer at the pylorus. Surgical diagnosis: Gastric ulcer at lesser curvature near pylorus and duodenal ulcer. (Dr. A. Gerster.) Oligoglobulia on one occasion. Polyglobulia on another.

Case XII.—M-T., aged 40, merchant. February 7, 1913. Ailing since ten years. At the beginning complained of constipation, neuralgic pains, headaches, eructation. Shortly after commenced to experience severe burning pain somewhat above the navel to right and lately also in the epigastric region, more to right. Pain radiates to the region of the back opposite the epigastrium. During six years he has been free from pain only for six weeks. The pain is frequently so intense that he cannot talk. On several occasions patient fainted on account of pain. At the beginning of his illness he used to be relieved from his "hot water pain" (his own term) by food. For many years patient has used one pound of bicarbonate of soda per week in order to relieve pain, which wakes him at night. Appetite has been always good. Stools lately appear clay-colored. Has lost somewhat in flesh. Patient is on a dry diet; cannot stand any liquids. He was refused by an insurance company, as sugar was found in his urine. P. H.: Had typhoid at the age of 17, and four years ago was operated for gallstone. Nothing was found, appendix removed, which proved to be healthy. He stood the anesthesia very badly. F. H.: Father died from gastric cancer. Examination: Great tenderness to right of navel. Blood pressure 130 mm. Second pulmonic accentuated. Urine: Albumin, positive; sugar, negative; sediment, a few casts. Occult blood twice positive. Polyglobulia present on two occasions. Operation (see discussion of cases).

Case XIII.—Miss M., aged 19. History given by Dr. Misslig. Has been ailing for several years. Pain in epigastric region more to right and in appendicular region. Pain radiates to lower angle of scapula and occasionally to lower back. She had an attack of "appendicitis," after which stools looked black. One and a half years after first attack of appendicitis had a second one. Patient was never jaundiced. Examination: Great tenderness in right parasternal line two fingers above navel, where rectus muscle is rigid. Tenderness at the spine at 12th lumbar vertebra, otherwise negative. Polyglobulia.

Case XIV.—S-r, L., aged 23. Seen February 19, 1913. Ailing one year. Pain across the abdomen, upper part. Constipation alternately with diarrhea. Examination: Great tenderness to right of navel, somewhat above. Polyglobulia found on two examinations. Occult blood twice negative.

Patients with polyglobulia from the Vanderbilt Clinic:

Case XV.—P-r, S., aged 57, no operation; seen first August 22. Ailing ten to twelve years with intense pain in epigastric region on and off. Pain is in no relation to food. Vomited lately on two occasions. Appetite poor. Night pain. P. H.: Pneumonia ten years ago; typhoid fever twelve years ago. Examination: Great tenderness in right parasternal line above the navel. *X*-ray plates taken by Dr. E. Leaming and reported as showing adhesions in region of duodenum. Occult blood negative twice. Polyglobulia present on nine examinations.

Case XVI.—P-i, B., aged 42. Seen first December 17, 1912. Barber. Ailing for two years with abdominal cramps and pain in the epigastric region, radiating to left shoulder. During his illness he had five such attacks. Duration of each attack about sixteen days. Lately he is free of pain from one to three hours after meals. He has no pain on empty stomach, but pain comes on as soon as he shaves the first patient. One of the attacks of pain came on after apparent peace for five months. He never vomited, nor has noticed tarry stools; was never jaundiced. Examination: Great tenderness in axillary line to right and at navel to right and left. *X*-ray report of Dr. E. Leaming. Hypermotility of intestines, which is frequently seen in duodenal ulcer. Occult blood negative on three examinations. Polyglobulia found on seven examinations.

Case XVII.—S-ky, R., aged 43, shoemaker. First seen at the clinic November 10, 1910. At that time he complained of a feeling of distress in the abdomen and of dark stools on and off for thirteen years. The diagnosis was put down at that time as gastroptosis and hyperacidity 25/1/13: Tenderness in epigastric region and right hypochondrium and about one finger above the navel to right side. Polyglobulia on four examinations.

Case XVIII.—D-z, H., aged 48, presser. Seen first January 11, 1913. Abdominal pain for several months. One week before vomited on a few occasions. Cannot sleep on account of pain. Examination: Tender spots to left of spine at 12th and 11th ribs and in region of right hypochondrium. Polyglobulia on four occasions.

Case XIX.—G-k, P., aged 31, traveling salesman. He complained of abdominal cramps for eleven years. Examination: Tenderness and rigidity in almost entire right half of abdomen. No leucocytosis. He was referred to the Roosevelt Hospital with the diagnosis: duodenal ulcer. Every one who saw the patient at the hospital made the same diagnosis. Dr. C. Peck was prepared to perform gastroenterostomy. There was found no ulcer, but a peculiar condition of the liver. The right lobe was reduced to less than one-third of its normal size, the left lobe appeared to be smaller than normal. Appendix was removed; it was normal. Patient has now the same symptoms. Polyglobulia on four occasions.

Case XV.—P-n, A., aged 30, liquor store, seen first January 25, 1913. Two and one-half years ago he had one evening a very severe attack of abdominal cramps. Has been well until two weeks ago, when cramps came on again. Examination: Great tenderness around the navel. Operation for duodenal ulcer was advised. Patient went to Mount Sinai Hospital to be operated upon. However, two hours before operation he changed his mind and backed out. Polyglobulia was found in the blood of this patient on two examinations.

Case XXI.—M-n, J., tailor. Seen first January 18, 1913. Four and one-half years ago he had severe attacks of abdominal pain, which was relieved by drinking hot water; lately he has pain from 2-3 hours after meals. Examination. (Dr. H. C. Thacher.) Deep tenderness above the navel. 3/11/13. Had lunch at 12 M., intense abdominal pain from 3-5 P.M. Polyglobulia on two examinations.

Case XXII.—K. M., tailor. First seen September 17, 1912. Has cramps in the region of umbilicus, coming on mostly at the middle of day, lasting a few minutes. Has similar cramps before moving bowels. Lately drinks very much water. Examination. Tenderness at navel to left. 14/1. At night had had a very severe attack of burning pain in the abdomen, could not sleep the whole night on account of pain. Occult blood twice positive. Polyglobulia on two examinations.

Case XXIII.—T-z, J., presser. Seen December 12, 1913. Ailing with indigestion since four months. Constant pain in right lumbar region. Examination. Tenderness in the region of the navel to right. Polyglobulia on two examinations.

Case XXIV.—G-b, M., tailor. Seen February 11, 1913. Patient is suffering for last eight months with attacks of burning pain in epigastric region. Since last two weeks pain comes on 3-4 hours after meals. Awakes at night on account of pain. One year ago had on two occasions bloody stools. Never vomited. Drinks very much water. Examination. Great tenderness above navel, to right, where rectus muscle is rigid. Polyglobulia on two examinations.

Case XXV.—A case of chronic pancreatitis with polycythemia, reported from the Vanderbilt Clinic (Medical Record, November 23, 1912).

Discussion of Cases.—Of our material, consisting of twenty-five cases, only six came to operation, and one of these six also to autopsy. The latter, as was mentioned already, proved to be chronic pancreatitis (Friedman[8]). Case IV, where tenderness could be mainly demonstrated in the appendicular region and only slight in duodenal region, showed at the operation many firm adhesions between gallbladder and duodenum and a firm, broad band around the first part of the duodenum. As gallstones were not found and as the removed appendix was found to be healthy, the possibility of a small duodenal ulcer which could have been missed at operation must be granted. Case XI proved to be gastric and duodenal ulcer. This patient was suffering from chronic indigestion for ten years. His chief complaints were: night pain, hunger pain, and he was also a user of bicarbonate of soda. Case X showed at operation a scar from a probable ulcer of mucous membrane on the posterior external wall of the duodenum with firm adhesions between gallbladder, duodenum, and colon. Case XIX is a peculiar one. This patient, who gave a history of attacks of pain for eleven years, showed on physical examination rigidity of the right half of the abdomen, but more in the duodenal region. As his blood did not show leucocytosis and as there were no tender spots in the right axillary line, nor in the scapular line, nor to left of spine, the diagnosis of duodenal ulcer was made. However, the operation disclosed a peculiar condition of the liver: the right lobe was in size less than one-third of a normal liver, the left lobe smaller than normal. Ulcer in duodenum was not found. Gallstones were not found. The removed appendix did not necessitate surgical interference.

The fact that duodenal ulcer may be present and not be found at operation is well known. The following case cited by Kemp may once more illustrate this: Clinical diagnosis: Cholangitis, peritonitis localis. At operation nothing was found. Autopsy: A funnel-shaped ulcer of the duodenum. The tissue of the head of the pancreas formed the base of the ulcer. Our patient with the atrophic condition of the liver has been seen repeatedly after the operation at the clinic. His symptoms and findings at physical examination: attacks of pain and tenderness in the duodenal region remained the same. These symptoms cannot be due to the atrophic condition of his liver. Case XII gave the most typical history of duodenal ulcer with the presence of occult blood on two examinations and pancreatic insufficiency, proven by complete analysis of the feces. At the operation, which was performed by Dr. H. Lilienthal, April 4, 1912, a large number of adhesions were found in the region of gall bladder, stomach, and colon. The duodenum could not be explored on account of the very many adhesions left. However, gastroenterostomy was done. A complication of duodenal ulcer with pancreatitis is just as conceivable as the complication of gallstones with pancreatitis, but it is also possible, as we shall note later, that the same cause which produces duodenal ulcer may at the same time be responsible for the causation of some forms of pancreatitis. The interpretation of *x*-ray plates gave very much support for the diagnosis of duodenal ulcer in Cases XV and XVI. Case VIII showed on two examinations positive tests for occult blood in the feces and a condition of intermittent pylorospasm, which is sometimes seen in duodenal ulcer. Case V gave a history of repeated melena and a positive reaction for occult blood on one occasion. Case VIII gave some findings. Patient I gave also a history of melena and a positive reaction for occult blood on one occasion. Case XXII showed two positive reactions. The report of *x*-ray picture in Case III can also be interpreted in the sense of duodenal ulcer. For the diagnosis of the rest of eleven cases one has to rely solely upon the histories and localization of pain in the duodenal region.

I shall not mention in the support of the diagnosis of duodenal ulcer the findings of hypersecretion and of high total acid values as in Case VI (free HCl—80, total—120), as I believe, that this tradition ought to be abandoned. One finds it so frequently in appendicitis, gallstones, renal colic and even in plain constipation, that by itself the findings of hypersecretion are meaningless. I found in the gastric contents of patients with constipation many years ago hypersecretion and again lately, and still they did not complain of pain, and, therefore, I believe that they did not have duodenal ulcer. The presence of occult blood in the stools is a more valuable diagnostic aid in duodenal ulcer, but gastric ulcer cannot be frequently ruled out. According to Moynihan occult blood is present only in 30 per cent. of cases of duodenal ulcer operated upon. It follows that the majority of duodenal ulcers do not bleed, at least manifestly. Bleeding in ulcer to any greater extent is just a complication as perforation of an ulcer. The localization of the pain, which has been assumed is more to the right of the epigastrium, is also frequently misleading. From all these considerations it can be easily comprehended why Miculicz[9] made the statement only ten years ago, that until that year the diagnosis of duodenal ulcer never was made correctly before operation.

The truth about the frequency and the diagnosis of this disease we learned only from English and American surgeons: Mitchell,[10] W. Mayo,[11] Mayo-Robson,[12] Murphy,[13] and especially from Moynihan. Moynihan does not hesitate to say that the diagnosis can be made before operation in 95-100 per cent. of the cases, and he illustrates it convincingly with his rich material. Why then such a difference in opinion between two eminent surgeons? Due attention was not paid to the history of the patient. Moynihan says: The history is everything for the diagnosis; everything else is of minor importance. And in the sense of Moynihan I believe our patients were suffering from duodenal ulcer, and in such patients polyglobulia was found. Patients IV and XI are so far exceptions, as in the first, after finding polyglobulia at three examinations, two months later anemia was found and in the second once anemia and on another occasion polyglobulia.

There is not a single mention of the occurrence of erythrocytosis in relation to duodenal conditions

in the whole literature. In three cases of Kemp from Copenhagen (the diagnosis of duodenal ulcer proved at operation) the hemoglobin showed 90, 95, and 115 per cent. Had he made counts of erythrocytes in these cases it is probable that he would have found polyglobulia. During the time of our studies counts of erythrocytes were made by us in different abdominal conditions: gastric ulcer, appendicitis, urethral calculi, hydronephrosis, gallstones, cirrhosis of the liver, and in various carcinomas of the gastrointestinal tract. In all these conditions anemia was found.

Blood.—The blood of our patients has been examined with greatest possible care. At the beginning of our work counts were made simultaneously in two chambers. After polyglobulia was found time after time in the cases of our series, this precaution was abandoned. Care was taken not to compress the finger or ear after puncture was made. The determinations of hemoglobin were made by the Sahli method in our private patients, by Fleischl's in clinical patients. At the clinic control examinations were made by Dr. S. Carluci, to whom I express here my hearty thanks. Viscosity of the blood could not be examined, but that it was probably high could be judged frequently from the slowness with which the drop reached the required mark of the pipette. In the majority of cases the white cells were counted. In Cases IV and XV hyperleucocytosis was found. In others normal counts. Not in a single case was leucopenia noted. Smears showed in several cases a few normoblasts, no megaloblasts. Eosinophiles were either absent or not above 1 per cent. in the cases in which a differential count was made. There was occasionally neutrophile leucocytosis. Nearly in all of the cases the lymphocytes were of small variety. Ten per cent. of mononuclears were found in Case XI, which proved to be gastric and duodenal ulcer.

In order to show the difference in the result of blood examination in gastric ulcer I shall refer to a case of typical gastric ulcer which I have lately seen at the Beth David Hospital. Hgl., 75 per cent.; R.B.C., 4,500,000; W.B.C., 4,100; poly., 41, 5 per cent.; S. L., 28, 5 per cent.; mono., 17, 5 per cent.; L.L., 7; eosino., 3 per cent.; baso., 1 per cent.; trans., 1, 5 per cent. (200 cells counted). These are frequent blood findings in gastric ulcers, which were proved to be such at operation. I shall refer to this difference more extensively in another communication. Leucopenia, slight eosinophilia, mononuclear leucocytosis. Leucopenia, mononuclear leucocytosis, as it is well known, is frequently found in exophthalmic goiter. The similarity of the blood picture in the two last-mentioned conditions, is, therefore, worthy of note. From blood films which have been studied in our series of cases, one is inclined to believe that the erythrocytes in them is perhaps due to slight hyperactivity of bone marrow, as in two instances surely normoblasts were seen. But the relative disproportion between the percentage of hemoglobin and the red cells has to be explained. Although the cause of the hyperglobulism, found in our patients remains, as in most polyglobulias unexplained, an attempt should be made to give a possible explanation.

At first it has been assumed that the findings of polyglobulia may be due to gastrosuccorrhea or hypersecretion, which condition was present, as seen from Table I in most of our cases. Such an explanation would be analogous to the interpretation of polyglobulia in diarrhea, which leads to losses of fluid from the blood.

However, this idea had to be given up on account of several reasons: in two cases of appendicitis in which gastric contents were obtained from 130-150 c.c. after test breakfast, polyglobulia was found on repeated examinations. In a patient with intermittently palpable tumor in the epigastric region, the occasional presence of which was due to pylorospasm, amounts of 80-120 c.c. were obtained on fasting without stagnation of food. The patient presented many nervous symptoms, due to the loss in a short period of time of three members of his family. Strange to say, he was a policeman. His blood showed from 3,500,000-3,900,000 red cells on many examinations. Only two months later, after he had been put on a roborant medication, the count of red cells showed 5,100,000. From these considerations gastrosuccorrhea or hypersecretion cannot be held responsible for the condition of polyglobulia found in our patients. Therefore, we had to look for another explanation, which, as will be seen, is in close relation to the results of Falta's experiments with adrenalin.

Falta[14] and his associates experimented at first on dogs with adrenalin. They injected ¾-1 mgr. subcutaneously and intravenously by the infundation method of Kretschmer-Straub,[15] which allows the introduction of small quantities of adrenalin during a longer period of time. Briefly the results of their experiments are the following: The number of erythrocytes in the cubic centimeters of blood increases rapidly after injections of adrenalin. They obtained an increase from 40-70-100 per cent. The increase occurs in like manner after subcutaneous injections. The intensity and the length of the reaction is variable, but a marked increase has been obtained in all dogs. Hemoglobin showed on the contrary scarcely any increase, and when a slight increase did occur, it was far below the increase of red cells. The specific gravity showed in normal dogs a slight increase. There was a marked leucocytosis, which was not due to infection, as the same occurred after aseptically conducted subcutaneous injections. The neutrophiles increased absolutely and relatively in all instances. The eosinophiles were diminished. There was a relative dimunition in the mononuclears; in one dog the decrease was even an absolute one. The hpyerglobulia was present in the peripheral capillaries, in internal organs and in the large vessels. The condition of polyglobulia lasted even as long as 31 hours. The cause of the duration has been explained by Exner,[16] Meltzer and Auer,[17] Boehme,[18] as due to the permeability of the vascular walls after adrenalin injections. But according to Falta and his co-workers the hyperglobulism is possibly due to increased production of red cells with diminished content of hemoglobin in the erythrocyte forming organs. The findings of normoblasts in the blood after injections with adrenalin in their experiments would speak, according to them, for such an assumption. In patients with different ailments in whom they injected adrenalin subcutaneously the findings and, therefore, their deductions were practically the same.

We repeated the experiments of Falta on five Vanderbilt Clinic patients with polyglobulia. The object was to see whether in such patients there would be a greater increase of erythrocytes after the injections of adrenalin. Only such cases were utilized for experiments in which it was possible to

make many counts before the injections were started with. We injected subcutaneously from half to one mgr. of adrenalin. The hemoglobin and red cells were determined before each injection, also blood pressure taken and urine was examined for sugar. It is a well-known fact that subcutaneous injections of adrenalin lead to a rise in blood pressure only exceptionally. A constant rise in pressure is only obtained in intravenous injections, and, as it was first shown by Auer and Meltzer, in intramuscular injections. As can be seen from Table II the blood pressure rose markedly in Patient XIX, in whom at operation atrophic condition of the liver was found. In the other four patients the bloodpressure became rather lower after adrenalin. The blood of patient 15 after a slight rise from 8,000,000-8,300,000 fell in about 44 hours to 4,500,000. When counts were made later he had again his usual polyglobulia. Patient 16 reacted 40 minutes after injection of 0.0005 adrenalin with a marked increase of red cells from 7,600,000-8,720,000. Such a high blood count he did not show at any time before injections were made, while one week later 1 mgr. did not produce such an increase. Patient 17, who lost in about 20 hours after 1 mgr. adrenalin 2,000,000 of red blood cells from his peripheral circulation, nearly gained back the original count 41 hours after injection. There is no doubt that in this patient a strong adrenalin effect had been obtained, as shown by the appearance of sugar in the urine and by the toxic symptoms. Patient 18 lost gradually in about 20 hours from 6,800,000-4,900,000 after 0.0005 adrenalin. Patient 19 responded immediately after 0.0007 adrenalin with marked rise in blood pressure. The increase of red cells was shortly after injection a slight one and a drop in about 19 hours to oligoglobulia. It should be mentioned here that Loeper[18] and Crouzon found after adrenalin injections first an increase and later decrease of red cells, which findings correspond somewhat to ours. But as in our cases there was already polyglobulia the slight rise of erythrocytes in some is possibly due to irritation of the red-cell forming organs, which is followed by exhaustion, and after some rest the original hyperglobulism was resumed.

If it is possible, as in the experiments of Falta, to produce hyperglobulism artificially, the question then arises whether a similar condition may occur in the human body, as a pathological condition, from an excess of adrenalin due to hyperfunction of the suprarenal glands. I believe, then, that the erythrocytosis found in our series of cases may be an illustration of such a possibility. As the histories in our patients corresponded to duodenal ulcer and some were proven to be such at operation, the relation of polyglobulia to pathological conditions of the duodenum is possible. It is then further possible that the organs which furnish the secretion of adrenalin are responsible for the causation of duodenal ulcer.

As in not one of our patients high blood pressure was noted, there must circulate in the blood of such patients an excess of adrenalin which may be too small to cause hypertension, but enough to produce an energetic action even in minimal quantities. In other words, if this assumption be correct, one can speak of hormone stimulation, as the definition of hormone is a chemical substance, which, being produced in one organ and circulating in the blood, is capable of stimulating in a certain manner another distant organ. The best proof of hormone action we have in secretin, a chemical substance, which is contained in the intestinal mucosa. Bayliss and Starling,[20] who gave the name "secretin" to this substance, scraped off the cells lining the mucous membrane of the upper part of the jejunum, rubbed them up in a mortar with sand and 0.4 per cent. hydrochloric acid, filtered the extract, and injected the filtrate into a vein. As a result a flow of pancreatic juice was produced. The principal agent, which was proved to be not a ferment and not a colloid, is diffusible through animal membranes and can be filtered through a gelatinized Chamberland filter. It may be compared to the active principle of the suprarenal gland, adrenalin, which has been obtained in a crystalline form and the chemical constitution of which has been determined. It has been found impossible to prepare secretin or a substance having a similar action on the pancreas from any tissue of the body other than the mucous membrane of the duodenum and jejunum. The effect of secretin seems to be limited to pancreas and liver.

Just as a secretory agent from the duodenum may act upon glands through the blood, just in the same way a chemical agent from a gland can act upon the mucous membrane of the duodenum. When, then, there is even a slight hyperfunction of the adrenals a pathological condition of the duodenal mucosa may set in, the condition must not be called necessarily hyperadrenalism, but hormone adrenalism. If one accepts the vascular theory in the causation of gastric ulcer, then one has great support for the assumption that adrenalin may cause vascular changes in the vessels of the duodenal mucosa. It is known that after feeding with adrenalin in rabbits sclerotic changes in the vessels do occur. Undoubtedly, the changes are caused only by absorption of small quantities. According to Bouché adrenalin does not become disturbed by pepsin hydrochloric acid or by pancreatin, and according to Comessati not even by the influence of bacteria in the intestines.

In the opinion of the majority of authors there is no reason to think of mere coincidence in explaining the action of this substance on the vessels of the rabbit. According to Biedl it is possible by fractions of one mgr. solution of adrenalin to note the beginning of changes in the vessels and the mode of developing adrenalin sclerosis. In older animals changes occur sooner, in younger, later. After injection of adrenalin abdominal viscera, especially the intestines, are not only hyperemic, but are frequently covered with extensive hemorrhagic patches. Pólya reports that in Buadpest, during the last fifteen years, duodenal ulcers and scars of such ulcers have been found ninety-one times in 9,272 autopsies; the ratio of duodenal ulcers to gastric ulcers in this series was found to be as 1:1,6, which corresponds well to the data given by Robson. So far as pathogenesis is concerned, Pólya thinks that the poor blood supply of the first portion of the duodenum plays an important rôle; he demonstrated this poverty in blood supply by *x*-ray photographs after injecting with bismuth vaseline. The frequency of duodenal ulcer in men may be due to the frequency of arteriosclerosis in men. The hyperacidity will help to develop ulcers from these hemorrhages. If we remember that adrenalin belongs to the group of disassimilatory hormones, which are growth retarding or growth prohibiting, the explanation why duodenal cancer

is so rare and gastric so frequent is then perhaps possible.

As the consideration of gastric ulcer is left for another communication, here it should be only briefly mentioned that in our opinion gastric ulcer may be due to the stimulation of an assimiliatory or growth-promoting hormone, perhaps a thyroid, and then the explanation of the occurrence of growth-like hyperthrophy of the pylorus as in benign hypertrophic pyloric stenosis and the frequent occurrence of cancer of the stomach may be explained in a somewhat more satisfactory way. It may be mentioned that an adrenalin action seems to oppose the growth of malignant neoplasms. Reicher saw a regeneration and necrosis in sarcoma of mice after injections of adrenalin in the region of the tumor. Based on these observations he went even so far as to recommend adrenalin for treatment of human tumors. If it be possible for minimal quantities of adrenalin to cause duodenal ulcer, then it may be also the cause of noninfective pancreatitis. Truly I had only one proved case of this condition in which polyglobulia was found, yet the following case of Brooks and Kaplan seems to speak for it. To a woman who was suffering from bronchial asthma over 20,000 injections of adrenalin were given in the course of three years. Patient died from hemorrhagic pancreatitis. There were diffuse capillary hemorrhages and resulting necrosis.

I would like to offer the following as conclusions of my observations:

1. Polycythemia is apparently a frequent phenomenon in cases of non-bleeding duodenal ulcer, proved such by operation, or answering the clinical syndrome erected by Moynihan and others.

2. No such phenomena are seen in gastric ulcer.

3. Injections of adrenalin in such patients is followed by a transient diminution in the red cells, but soon afterward the polycythemia asserts itself.

4. The injections of adrenalin in dogs produce a polycythemia, which apparently is due to a lesion of the bone marrow.

I assume that the causes of polycythemia in my cases are intimately connected with the causes of duodenal ulcer, and may be due to some alteration in the secretion of adrenalin.

5. It may be assumed that duodenal ulcer is perhaps a trophic disorder due to some disturbance in the secretion of adrenalin. My hypothesis is that adrenalin in such cases acts hormone-like in a specific manner upon the vessels of the duodenal mucosa and produces the changes that finally lead to the appearance of ulceration.

Note.—Since reading this paper I have been able to obtain more proof of the presence of erythrocytosis in the blood of patients with non-bleeding duodenal ulcer. This constitutes an essential addition, as reports which are chiefly based upon medical material are open to criticism, no matter how accurately histories were taken and data obtained:

Case XVI (from my own series).—Patient entered the service of Dr. A. G. Gerster at the Mt. Sinai Hospital. Blood examination at the laboratory of the hospital showed hemoglobin 120 per cent., red blood corpuscles 5,500,000. In his surgical report of May 2, 1913, Dr. A. A. Berg stated that there was duodenal ulcer. He performed gastrojejunostomy with exclusion of the pylorus.

Case XVIII.—Patient had one severe intestinal hemorrhage in the beginning of May and another one with hematemesis in the latter part of the same month. On May 25 an *x*-ray picture was taken and a fluoroscopic examination made by Dr. S. I. Hirsch, who reported hypermotility of the bowels. On May 29 patient was picked up in his house by a settlement nurse and sent to the Mt. Sinai Hospital (service of Dr. Morris Manges). I am indebted to the house physician for the following data obtained during patient's stay in the hospital: May 30.—Test meal. 120 c.c., normal in appearance and odor. Free hydrochloric acid 55. Total acidity 85. Occult blood: Benzidin +; guaiac —. May 31.—Feces: Benzidin and guaiac +. Hemoglobin 30 per cent. Red blood corpuscles 1,770,000. June 1.—Feces negative for blood. June 4.—Feces, benzidin and guaiacol positive. June 6.—Hemoglobin 55 per cent. Red blood corpuscles 3,016,000 Although the patient was not operated upon, there can hardly be any doubt that our diagnosis of duodenal ulcer, made in February, was correct. The blood examinations, however, made by myself and Dr. S. Carloci, showed erythrocytosis at that time. There was no history of hematemesis or melena at that time.

I wish to cite only two additional cases as briefly as possible:

Case XXVI.—R. I., referred by Dr. C. Goodman. For many years attacks of gnawing pain in epigastric region, hunger pain, and night pain. Physical examination. Tenderness in epigastric region, more intense toward the right side. Gastric analysis showed hyperacidity. Blood. April 24.—Hemoglobin 68 per cent. Red blood corpuscles 5,530,000. April 26.—Hemoglobin 70 per cent. Red blood corpuscles 6,630,000. Diagnosis.—Duodenal ulcer. Surgical report by Dr. C. Goodman: Adhesions between gallbladder, liver, and first portion of duodenum. Scar in the first portion of duodenum. Stomach normal. No stone in gall-bladder. Gastrojejunostomy with exclusion of pylorus. (May 1, 1913, Beth Israel Hospital.)

Case XXVII.—A. O., 34; seen March 23, 1913. History of abdominal pain in epigastrium for last six years. Physical examination.—Tenderness to right from umbilicus and on one occasion rigidity of left rectus muscle in the umbilical region. Blood: March 23.—Red blood corpuscles 7,610,000. March 27.—Red blood corpuscles 6,200,000. Hemoglobin 90 per cent. May 5.—Red blood corpuscles 5,600,000. Hemoglobin 90 per cent. White blood corpuscles 9,800. Polymorphonuclear leucocytes 58 per cent. Small leucocytes 37 per cent. Large leucocytes 1.5 per cent. Transurinal leucocytes 1.5 per cent. Eosinophiles 1 per cent. Basophiles 1 per cent. Occult blood in feces, negative. Diagonsis: Duodenal ulcer. Surgical diagnosis: Duodenal ulcer (June 2, 1913, Beth David Hospital), Gastrojejunostomy with exclusion of pylorus. (Dr. A. A. Berg.)

The blood findings of some patients with gastric ulcer should also be added:

Case XXVIII.—Sam B., 34. An ulcer found near the pylorus (operation by Dr. Gerster, December 21, 1912). Hemoglobin 70 per cent. Red blood corpuscles 3,900,000. White blood corpuscles 4,800. Polymorphonuclear 46 per cent. Small leucocytes 30 per cent. Large leucocytes 3 per cent. Mononuclear 17 per cent. Eosinophiles 4 per cent.

Case XXIX.—T. B., 52. Gastric ulcer at the lesser curvature, size of a silver dollar. (Dr. Gerster.) January 14, 1913. Blood: Hemoglobin 55 per cent. Red blood corpuscles 3,400,000. White blood corpuscles 4,840. Polymorphonuclear leucocytes 44 per cent. Small leucocytes 36 per cent. Mononuclears 15 per cent. Eosinophiles 4.5 per cent. Basophiles 0.5 per cent.

Case XXX.—J. G., 38. Gastric ulcer at pylorus, extending to lesser curvature. (Beth David Hospital, June 21, 1913.) Dr. A. A. Berg. Hemoglobin 70 per cent Red blood corpuscles 4,520,000. White blood corpuscles 0,880. Polymorphonuclear leucocytes 52 per cent. Small leucocytes 31 per cent. Mononuclears 12.5 per cent Transurinals 1 per cent. Eosinophiles 3.5 per cent.

With the exception of anemia in chronic gastric ulcer and polycythemia in chronic duodenal ulcer, I would like to call attention to the presence of relative eosinophilia in the first condition and to scanty eosinophilia (not over 1 per cent.) in the latter.

MEDICAL SCHOOL INSPECTION AND THE GENERAL PRACTITIONER.

BY MARIA M. VINTON, A.M., M.D.,

BRIGHTWATERS, L. I., N. Y.

NEW JERSEY STATE CHAIRMAN PUBLIC HEALTH EDUCATION COMMITTEE OF THE A. M. A., MEDICAL INSPECTOR IN N. Y. HEALTH DEPARTMENT

SINCE Medical School Inspection, instituted under the Health Department, has brotdened out its work and has begun to accomplish great things in improving the health of the school child, this very progress has opened its work to misconstruction and to attacks from some members of the medical profession, who think themselves unfairly treated and deprived of paying patients by the work done in schools. They have seen fit to depreciate its work and methods, and to bring forward the claims of the general practitioner to do this work outside the schools. As a medical inspector under the Health Department for the past fourteen years, the writer claims to be familiar with the facts of this work. With a force of but 92 inspectors, each of whom is expected to be responsible for the care of 9,000 children, some of them working in districts where it is necessary to cover large areas and spend considerable time in trains and trolleys going to and from their work, it is rather to be wondered at that so much has been accomplished. It should be remembered that this work has advanced from the time when the visit of the inspector was unwelcome and regarded by the school principal as an interruption which would result in a lessened attendance, to the time when his visit is welcomed, and many demands are made on his time by principals, teachers, and even parents, who think it his duty to minister to all the child's ills, surgical or medical. Much time must be consumed in diagnosing and following up cases of contagion found in the classrooms and reported by the teachers, which remain at home without the attendance of any physician. The deficient child is brought to the medical inspector for advice and assistance in determining his mental status, and whether he should be a candidate for examination for an ungraded class. When an anemic class is to be formed it is the medical inspector who is asked to indicate suitable pupils for entrance to it. The author has given several afternoons of her own time to selecting and visiting such children to assist in forming the first open-air class in her district, previous to the examination before the Board of Education specialist. The whole neighborhood thinks that the school nurse should minister to its ills, and many unjustified demands are made upon her time when she goes to visit in the children's homes. Examinations of heart and lungs, before pupils can enter for the athletic meets, must be made spring and fall, and these take up considerable of the inspectors' time. From principal and truant officers come requests for certificates to be used in court, and statements which will allow of the discharge of children from school lists on account of prolonged sickness. After the suspected contagious cases and the cases for advice of various kinds are disposed of there is but half the morning left for the regular work of physical inspection.

The largest class in every school is 1A, the beginners, and each of these must be examined and his condition recorded on Health Department and school record cards. Only after these are disposed of can the special eye and throat cases be reached. Nevertheless, an active and interested inspector can get time for special examination of many of the older children who show symptoms of eyestrain, defective breathing, curvatures, orthopedic and other deficiencies which render them unable to compete with the normal child. With the present number of inspectors it would take many years to make thorough tests of all the older pupils. It has become the fashion for the principal to refer to the Medical Inspector disciplinary cases, the bad boys of the school, the boys who have bad habits, and to ask if the medical department cannot do something to correct these evil tendencies. Of course many of these bad children are really mentally deficient, but there are others in whom no mental or physical defect can be discovered who yet remain bad and are truants.

At a recent meeting of the Neurological Section of the Academy of Medicine we heard a great deal about what the general practitioner should do for the school child. In my own suburban district the general practitioner has proven a broken reed to lean upon. For some years children found to have physical defects were referred to their family physicians for treatment of adenoids and tonsils, for fitting of glasses, and treatment of orthopedic difficulties.

There were no convenient dispensaries to which the poor children could be sent. Few of them had any family physician, the severest types of sicknesses being treated by whatever physician was most convenient at the time, the less severe ones being left to nature to cure. The result of this was that only the children of richer parents got any attention, and the needs of the poorer ones were not attended to by the parents. Only since the establishment of the Health Department Clinics for School Children has any systematic treatment of eye and throat troubles been possible. Now, thanks to the work of the Health Department, it has been possible to get systematic examinations made for glasses, treatment given, and op-

erations done for throat and nose difficulties. I could cite cases in which children, formerly truants and mischief-makers in their classes, have changed to interested students and regular attendants after the remedy of their defects by properly fitted glasses. Under the old methods the glasses would have been fitted by the practising optician, and many pairs of such glasses were laid on the shelf because the child could not see any better nor as well with them as with his unaided eyes. It has been shown that the general practitioner is neither ready nor competent properly to test eyes; also that when he operates for the removal of adenoids and tonsils he often fails to make a good operation and leaves the child worse off than before. Very little treatment of any value is obtained in special cases by recourse to the general practitioner, the very man who complains that his patients are being taken away from him by the Health Department. It would seem that he has very little cause for complaint, and that had he found out the defects of the child and remedied them it would not have been necessary for the Medical Inspector to call the attention of the parents to them.

Under the present methods the children needing treatment and unable to pay for it, instead of being neglected and allowed to leave school without defects remedied, are gathered together by the nurse, directed to the proper clinic, and the defects are remedied by operation, or by properly fitted glasses. They are tested, when necessary, under the influence of atropin instilled the day before. An amusing case arising from the use of these drops occurred lately in the writer's district. Atropin drops were given to the mother of twin boys whose eyes needed to be tested, to take home and instil the night before the examination. The mother had an old keratitis, and another member of the family some trifling eye difficulty. The mother thought that if these drops were good for one member of the family they must be for all. So all four members were treated with them. In the morning, the nurse was sent for post haste, as they were all equally unable to see, and their occupation of awning making was rendered impossible for the time. Most excellent results have been obtained among poor children by the systematic cooperation of the Inspector, the nurse, and the Health Department Clinic.

On the occasion referred to above a paper was submitted to the Academy of Medicine reciting remarkable results obtained by the systematic testing of the backward and unruly members of a number of schools by a private practitioner. Charts of these cases were thrown on the screen. I would submit that in any large school similar results could be shown had the Medical Inspector the time to make a collection of the cases under his observation. The chief obstacle to this kind of work is the lack of time of the inspectors. If the best results are to be obtained the number of medical school inspectors should be trebled. The second obstacle is the opposition of parents to operative procedures and the wearing of glasses by children. A mother said to the writer: "I would rather have my daughter go blind than have her wear glasses." This girl was far behind her grade, and unable to do her work. She looked sidewise at the board when she wished to see it. She has even been sent to the inspector with a question of her mental ability. So she goes on through her school course, promoted by courtesy and according to size, handicapped by a severe astigmatism, all because she needs a "new set of parents." Of course only public health education of the masses can set aside this condition of things.

In cases of defective hearing the chief obstacle to a cure is the inability to secure systematic and steady treatment of the running ear until the discharge has ceased. Many a child becomes deaf from such neglect, who might have had useful hearing. What is needed in the schools is more workers, more nurses to visit parents and arrange for visits to the clinics; more medical inspectors, raised above the bread-and-butter question by the payment of a living wage, allowing of suitable support without the necessity of entering into general practice. There are needed men who will take thorough special courses in diagnosis of eye, ear, and throat conditions, in treatment of orthopedic defects, and in methods for development of curved spines and paralyzed limbs. The orthopedic defects are the most neglected of all at present.

The medical school inspector should be a specialist in whatever pertains to the perfect physical development of the child. The work of the Health Department in school inspection has been a steady growth, especially since the Division of Child Hygiene was created, under a progressive Director, in the person of Dr. S. Josephine Baker. As far as the appropriations for this work have allowed advances have been steadily made. The medical and the general public have begun to wake up to what has been done, and the former to complain of unfair treatment by the department. On the contrary what is needed is double the number of inspectors, more and better men, and more women inspectors. These men and women should give their entire time to the school work. To them should be sent the mentally deficient children for examination and Binet testing, instead of to a Board of Education specialist. There should be sufficient study by the inspectors of mental conditions and feeble-mindedness to enable them to carry out this branch of the medical work. Then, as soon as a defective mentality was discovered it could be placed in the ungraded class without any delay, or any question of the parents' consent. This would be simply part of the school routine, instead of being a matter of a special examination by the physician, who would come but once or twice a year. Instead of waiting for many months or even a year before he could begin the manual training he needs, while he loses valuable time in the regular grades, he would be classified and graded as a matter of school routine and begin his training at once. The establishment of a special class of medical inspectors under the Board of Education seems to the author to be a mistake. All this work should be under the Health Department, a part of the regular medical inspection.

It would seem to the author, in conclusion, that it is time for the general practitioner and the family physician, so far as he exists, to cooperate heartily with the medical school inspector, to go hand in hand with him, instead of finding fault and placing all possible obstacles in his way. He will gain much more in the end, in reputation as well as in pocket, if he will himself "get on the band wagon" instead of throwing stones at the other workers.

THE WASSERMANN REACTION AMONG THE NEGRO INSANE OF ALABAMA.*

By R. R. IVEY, M.D.,

TUSCALOOSA, ALA.

ASSISTANT PHYSICIAN ALABAMA INSANE HOSPITALS.

THE importance of syphilis as an etiological moment in psychopathology and the almost total inability to secure clinical data sufficient for a reasonably definite diagnosis of the condition in the vast majority of patients admitted to the Mount Vernon Hospital has been the incentive for doing the test on each patient in the hospital. I do not mean to designate as "syphilitic psychosis" every case in which the test was found positive. On the contrary I think we may safely presume that in some cases syphilis has been superimposed on an already disordered nervous system. Two methods have been used on each specimen of blood, viz., Wassermann's and Tschernogubow's.

The latter utilizes the native complement and amboceptor present in human serum which makes it necessary to use the serum in the fresh or active state. In my series about 3 per cent. of the specimens examined showed a total absence of anti-guinea-pig amboceptor, consequently the pig cells were not hemolized and no reading could be made. This, however, can be obviated by adding a known negative serum which has been inactivated, since the process of inactivation does not materially disturb the amboceptor content. The antigen used in both systems was an extract of normal tissue fractionated in alcohol, ether, and acetone.

The following objections to the original method of Wassermann are offered by different workers: (1) The presence of anti-sheep amboceptor in many human sera; (2) the use of serum in the inactive state. Both of these conditions tend to render an otherwise positive reaction negative, since if all the complement present is not deviated that small amount which is left uncombined in the presence of the anti-sheep amboceptor added to the test and also the native anti-sheep amboceptor, hemolysis will take place to a greater degree than it should, depending of course upon the amount of native amboceptor. Thus a negative reading is quite possible with a serum which is weakly positive. The process of inactivation has been shown to reduce greatly the antibody content of syphilitic sera, consequently with a serum in which the antibody content is already low these two factors acting together might easily give a negative reading. Principal among the objections to the Tschernogubow method is the fact that the natural complement and amboceptor are irregular in quantity and there is difficulty in placing them under exact quantitative regulation. This, however, can be overcome by using a series of antigen controls instead of only one, and using a decreasing amount of patient's serum in each tube. This system seems to be more delicate and gives a higher percentage of positives than the Wassermann. To use the two methods in conjunction, carefully weighing the results in each instance, seems not a bad procedure.

Among the 706 patients examined 64, or 9 per cent., had at some previous time had one or more attacks of pellagra. Of these 19 were men and 45 were women. There were 6 positives and 13 negatives, or 36 per cent. positives, among the male pellagrins; among the female pellagrins there were 19 positives and 26 negatives, or 42 per cent. positives.

As will be seen later this is a higher percentage of positives than was found among the population of the hospital taken as a whole. The clinical signs of syphilis among the pellagrins did not differ materially from that found in those who had not had pellagra.

The total number of females examined was 349, of which 102, or 29 per cent., were positive. The total number of males examined was 357, of which 90, or 25 per cent., were positive. I think the higher percentage of positives among the female patients can be explained when we consider the general moral tone of the negro women found in this institution, and also by the fact that fewer cases of syphilis among negro women receive proper treatment than among the negro men.

There was nothing characteristic about the mental conditions of those who were positive or negative save one feature which seems worthy of mention, viz., there were 17 cases of general paresis, *all of which gave a positive reaction.*

Among the 90 males in whom the test was positive, 48 showed clinical signs of syphilis, such as adenopathy, pigmentation of skin, exostoses, etc. There were 102 positive tests among the females, 49 of whom showed similar clinical evidences of syphilis.

One hundred patients whose test was negative were selected and examined for the presence of adenopathy and it was found to be present in twenty. There were no other clinical signs present, however.

A classification of the mental conditions of all patients examined is hereto appended (classified according to table used in this Institution). It will be noticed that no attempt is made to classify the different psychoses present in epileptics, they being classified merely as "Epilepsy."

TABLE SHOWING PSYCHOSES AND THEIR SERUM REACTION.

*Read before the Jefferson County Medical Society, Birmingham, Ala., August 4, 1913.

The Origin of Urinary Albumin.—N. Krasnogorski concludes on the basis of experiments performed with the aid of precipitin and complement-deviation methods that the albumin excreted in the urine in the albuminuria of infancy does not contain any of the specific groups characteristic of the dietic albumin, but is derived entirely from the tissue protein.—*Zeitschrift für Kinderheilkunde.*

The Histopathology of Acute Poliomyelitis.—R. Walter draws his conclusions from four cases studied during the Westphalian epidemic of 1908. He notes that there are two stages of acute inflammation, the lymphocytic and the plasmocytic, depending upon the predominance of lymphocytes or plasma cells. A regular finding is the presence of inclusions in the ganglion cells which inclusions the author regards as specific.—*Deutsche Zeitschrift für Nervenheilkunde.*

COLISEPSIS AND ITS CLINICAL PICTURE.

THE ubiquity of the colon bacillus, its variability in virulence, and the multiple rôle which it may play in the pathology of the human body, are facts which have been firmly established in modern clinical medicine. There are many problems concerning this microorganism which still await solution, particularly the laws governing its virulence, the differentiation of its numerous strains, and the clinical phenomena accompanying the local and general infections which it produces. A voluminous literature has arisen during the past few years concerning the colon bacillus and its pathogenic properties. For a review of this literature in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. I, No. 3, we are indebted to Ludwig Fejes of Budapest.

Regarding the localized infections caused by the colon bacillus little need be said. It has been established that this microorganism, which finds a natural and peaceful habitat in the human intestine, may, when the latter becomes the seat of inflammatory or ulcerative processes, penetrate through its wall and then take on most pronounced pathogenic properties. One may then speak of an endogenous infection. But ectogenous infection though less common than the latter is not at all rare, as may be gathered from the numerous instances of waterborne epidemics of colon bacillosis, and of infection from putrid meat and other foods. The more common endogenous infections occur through three main avenues: the intestinal wall, the biliary passages, and the urinary tract. Cases are no longer considered rare in which the colon bacillus is detected as the offending organism in peritonitis, cholecystitis, liver abscess, pyelitis, empyema, and meningitis. In these and many other local pyogenic processes the colon bacillus may be alone or in company with other microorganisms.

In contrast to the localized infections caused by the colon bacillus, comparatively little has been written on the subject of general sepsis produced by this microorganism. The reason for this paucity of knowledge is not far to seek. In both localized and general infections with the colon bacillus blood cultures are as a rule negative. Nevertheless, despite the absence of this valuable diagnostic aid, the clinical picture of colisepsis is one that is sharply defined and readily recognized. The most important symptom is the high fever which is accompanied by severe rigors. The temperature curve is usually marked by sharp remissions. The rate of the pulse corresponds to the height of the temperature, though occasionally the relative bradycardia of typhoid fever may be simulated. Local foci of inflammation or suppuration can often be detected: endocarditis, bronchopneumonia, empyema, and suppurative meningitis may be present. Nervous symptoms may range all the way from a typhoid-like apathy to a marked delirium. There is a moderate leucocytosis, the count varying from six to fourteen thousand. In spite of this characteristic clinical picture, the exact diagnosis of colisepsis is surrounded with difficulties. The rapid destruction of the colon bacilli in the blood accounts for the frequent negative results of bacteriological examination. Fejes has succeeded most frequently in obtaining a positive blood culture by removing the specimen of blood from the median basilic vein just after the rise of temperature that follows a chill. Animal inoculation often enables one to obtain positive evidence of the presence of colon bacilli when cultural examination fails.

Of eminent importance is the study of the portal of entry of the colon bacilli into the general circulation. A lesion of some part of the alimentary canal may provide this gateway. Fejes has observed two cases of colisepsis following a simple angina. In one of these cases there developed a cholangitis with enlargement of the liver, accompanied by chills and wide excursions of the temperature curve, and later there developed a right-sided purulent pleurisy from which the colon bacillus was isolated. This microorganism is one of the most frequent causes of peritonitis. The enterogenous forms of colisepsis may closely simulate typhoid fever. One important point in the differentiation between the two conditions, as emphasized by Schottmüller, is the absence of a roseola in the former. The intestinal lesions of typhoid fever provide, however, an easy access of the colon bacillus into the general circulation, with the result that many cases of typhoid fever are complicated by colisepsis. The same complication occurs in various forms of diarrhea and dysentery and in Asiatic cholera. The constancy with which the colon bacillus has been found in the blood in cases of cholera led Emmerich to mistake this microorganism for the specific cause of cholera and to name it the *"Bacillus neapolitanus."*

The biliary passages furnish a common pathway by which the colon bacillus reaches the general circulation. Indeed, Naunyn attributes most cases of cholangitis to an infection with this microorganism The rôle of the colon bacillus in acute ascending and acute hematogenous infections of the kidney is so well-known that it need only be alluded to. Colon bacilli are the main cause of the so-called "catheter fever." The work of Albarran and many others has served to demonstrate the overwhelming importance of the colon bacillus in the pathology of the urinary tract. The possibility of the occurrence of a colisepsis during the puerperium should be borne in mind.

The natural history of the colon bacillus is still to be worked out. In view of the large varieties of localized infections which it may produce, the fact is remarkable that the average individual does not more frequently become a prey to the myriads of these microorganisms which swarm in the intestinal tract—a number so large that from twelve to fifteen milliards of them are voided daily.

BLOOD TRANSFUSION.

With the modern perfections of technique, the direct transfusion of blood has been robbed of most of its dangers and has come into favor as a therapeutic agent for many conditions. One of the greatest sources of danger has always been the possible incompatibility of the bloods of the recipient and the donor. In order to avoid this danger it has become the practice to test the two bloods for mutual agglutinative and hemolytic properties except in those instances where the transfusion was an emergency measure. Any one who has done many of these tests has found that the reaction *in vivo* has nearly always been much more intense than the reaction *in vitro* especially as regards the hemolytic effect. Hemolysis practically always follows a transfusion whether or not it was evident in the test-tube. The seriousness of this hemolysis has been a matter of debate but until recently it was thought that its principal disadvantage was that the donor's red cells were broken down so quickly that the transfusion resulted in little benefit and many of the beneficial results have been ascribed to substances in the serum.

In order to determine, if possible, what the effect of such incompatible blood would be Ottenberg, Kaliski, and Friedman experimented with dogs. They found (*Jour. Med. Research*, 1913, xxviii, 141) that isoagglutination and isohemolysis occasionally occur between the bloods of apparently normal dogs. They are closely connected and hemolysis never occurs without agglutination. Two pairs of dogs were selected whose bloods showed the most intense incompatibility, and transfusion was performed between them. In one pair after two transfusions and in the other pair after four, the recipient became ill, suffered from dyspnea and internal hemorrhages and died in twenty-four hours. Autospy showed numerous hemorrhages in the various organs, phagocytosis of red blood cells in the spleen, and hemoglobin casts in the kidneys. In one dog a blood smear made shortly before death showed a very large number of nucleated red cells together with poikilocytosis, anisocytosis, and polychromatophilia. When transfusions were done between other pairs in which the preliminary tests were negative or only weakly positive, the results were negative. They conclude that the direct transfusion of red cells that are laked and agglutinated results in the solution of the transferred blood and an intense intoxication of the recipient. As a partial effect of this intoxication there appeared at one time a blood picture which in some respects closely resembled that in pernicious anemia. They think that the changes must have been due to some peculiar toxic effect, on the bone marrow, of hemolytic blood destruction.

The lessons to be derived from this work are in part quite obvious. In view of the meager information which has been apparently derived from blood tests there is a distinct and growing tendency to abandon them, especially in emergency cases. This is altogether wrong and the desirability of such tests should be emphasized. The treatment of pernicious anemia by means of repeated transfusions of small quantities of blood has met with at least temporary success in some cases and yet we find that if the bloods are incompatible the resulting picture may resemble that of pernicious anemia. The line of demarcation here is evidently a shadowy one. One of the interesting side problems would have to do with the question as to whether the normal destruction of the red cells in the body is accompanied by the liberation of a toxin which is able to stimulate the bone marrow to replace the lost cells.

OBSERVATIONS OF AN INTERNIST DURING THE BALKAN WAR.

By the term "internist" is naturally indicated not so much the "general practitioner" as the physician who treats exclusively the maladies of the blood and thoracic and abdominal viscera. The internist shares this field to an ever-increasing extent with the surgeon; but in the time of epidemics he naturally becomes the epidemiologist. That is in part, perhaps, because the blood plays so conspicuous a rôle herein; but further because in all ages the control of epidemic affections is left to the most liberally educated medical men, who are naturally sanitarians and concerned above all with prophylaxis. This viewpoint was well illustrated by Böhme at a meeting of the Medical Society of Kiel (*Muenchener medizinische Wochenschrift*, September 9). The author took cognizance among other features of typhoid fever and bacillary dysentery—nominally medical affections. There were discovered very many healthy carriers of both diseases. The typhoid patients were prone to develop a purpuric roseola, which led to a strong resemblance to typhus fever. The two affections, typhus and typhoid, are differentiated largely by the blood count; since in the first named there is leucocytosis, while in the latter leucopenia obtains. Dysentery pursued a mild, subacute course. Relapsing fever was occasionally brought in from the Turkish side and was invariably jugulated by salvarsan. Variola appeared in the unvaccinated Turks in a severe and fatal form. The fairly well vaccinated Servians developed varioloid for the most part. General vaccination of Turkish captives, the troops, and the community in general arrested the spread of smallpox. Difficulty was experienced in differentiating varioloid and varicella. In the former, however, the constant leucocytosis with marked increase of large mononuclear cells has marked diagnostic significance.

CAUSES OF URINARY FEVER.

It has generally been recognized that so-called urinary fever may appear either spontaneously or after instrumentation, etc. It may also assume a chronic form when there is constant slight infiltration of urine in stricture cases; but, generally speaking, the term is not applied to the consequences of rupture of the urethra or bladder with notable infiltration of urine threatening gangrene.

At a recent session of the General Medical Society, Cologne (*Münchener medizinische Wochenschrift*, September 16), Thelen summed up the subject as follows: the commonest form of urinary fever is that induced by a trauma of the urethral mucosa as caused by instrumentation. Through this port of entry the usual bacteria of infected urine or unclean instruments pass into the blood paths. However, other factors may be required to set up the fever, as imperfectly functionating kidneys, increased nervous reflex activity, and general diminution of resistance. So-called spontaneous urinary fever is seen in stagnation of the urine from any cause—stricture of urethra, prostatic hypertrophy, etc. Some stricture cases show a daily fever. In all such mechanical retention cases the problem is naturally one of drainage. In cases due to minute traumatism the problem becomes one of prophylaxis in connection with the proper use of instruments.

Elastic Skin.

This condition is almost hopelessly confounded in the clinic with cutis laxa, essential hypertrophy of the skin, and numerous other conditions, so that any attempt to isolate merely resilient normal integument should be welcome. One seeks a physiological and not an anatomical anomaly. At a meeting of the Strassburg Society of Military Surgeons held last July (*Deutsche medizinische Wochenschrift*, September 4) Mentberger described a case of extensible and resilient skin in a healthy young man. When the integument of the arm, neck, etc., was pinched up into folds there was an immediate return of the parts to their normal position as soon as the elastic fibers were permitted to resume their activity. This type of skin is normal in puppies, kittens, and anthropoid apes. Sections of skin show under the microscope no increase in elastic fibers. It is said, however, that the derma in these cases is myxomatous rather than fibromatous—a colloidal, formless tissue. The condition appears to represent a persistence of the embryonal state, and this is further borne out by the occasional familial incidence of cutis elastica.

Salvarsan in Actinomycosis.

Actinomycosis is not an affection which one would expect to yield to salvarsan. Ehrlich, when asked about this relationship replied that he knew only of a few cases of improvement related by Umber. Nevertheless, Pfloeger, before a recent session of the Aertzlicher Verein, Munich, (*Münchener medizinische Wochenschrift*, September 16), reported a clean-cut case of typical actinomycosis promptly cured by neosalvarsan. There was present a focal reaction. No benefit had accrued from a former course of potassium iodide. Stubenrauch had treated a case with the latter salt, salvarsan, and *x*-rays without making the slightest impression upon it.

News of the Week.

Gifts to Columbia.—The Trustees of Columbia University, New York, at their meeting on October 6 announced among others the following gifts: From Mr. Clarence H. Mackay, $2,500 for surgical research; from an anonymous donor, $1,000 for salaries in the Department of Physiology; from the family of the late Mr. W. Bayard Cutting, $200,000 to constitute a fund for the maintenance of traveling fellowships open to graduates from the university, including the College of Physicians and Surgeons.

Lower Death Rate.—For the week ending October 4, the death rate in New York City was 12.12 per thousand as compared with 12.85 for the same week of last year, the total number of deaths being 1,248 and 1,274, respectively. During the week only two deaths from scarlet fever and two from measles were reported. Diphtheria showed an increase of seven deaths, whooping cough of five, and typhoid fever of six, as compared with the same week of 1912. There was, however, a decrease of thirty-one deaths from tuberculosis, and of thirty-eight from nephritis. Heart disease showed an increase of twenty deaths.

Harvey Society Lecture.—The second lecture of the present course offered by the Harvey Society will be given at the Academy of Medicine, New York, on Saturday evening, October 18, by Prof. Adolph Schmidt of the University of Halle, whose subject will be: "Severe Anemia in Gastrointestinal Diseases."

Dr. Bulkley's Lectures.—The Governors of the New York Skin and Cancer Hospital, Second avenue and Nineteenth street, announce that Dr. L. Duncan Bulkley will give a fifteenth series of clinical lectures on diseases of the skin in the Out-Patient Hall of the hospital on Wednesday afternoons, beginning November 15, 1913, at 4:15 o'clock. The lectures will be free to the medical profession on the presentation of their professional cards.

Clinical Lectures in Genitourinary Diseases.—Beginning November 3, 1913, and continuing for a period of four months, Dr. Bierhoff will give a series of clinical lectures and demonstrations on Genitourinary and Venereal Diseases, including the modern methods of diagnosis and treatment, every Monday evening, at 8:30 o'clock, at the West Side German Dispensary, 328 W. Forty-second street, New York City. The course will be free to physicians and advanced students in medicine.

Vital Statistics.—During the month of August, 1913, the number of births reported in New York State was 18,793, while the deaths reported during the same time numbered 11,827. In New York City alone the births during that month numbered 11,326 and the deaths 5,841, an excess of births over deaths of 5,485.

Typhoid Epidemics.—The Health Commissioner of New York City has announced that the origin of the recent cases of typhoid fever on the east side of the city has been traced to the milk sold by a dairy company in that part of the city. The sale of this company's milk has been stopped and a thorough investigation, extending to the farm maintained by the company, is being made. During the week ending September 27, 183 new cases of typhoid were reported, as compared to 42 cases for the corresponding week of last year.

At least one-half of the members of the Rhode Island party which attended the Perry Centennial celebration at Put-in Bay on September 8 to 15, were said on October 9 to be suffering from typhoid fever. The cases are scattered all over the State, and the condition of some of the patients is said to be critical.

Plague Rat in Seattle.—An order to destroy a structure known as the "old Seattle Hotel," in Seattle, Wash., was issued by the Commissioner of

Health on October 9, because a rat caught in the building was found to be infected with bubonic plague. Adjoining buildings may also be razed.

Cholera in Turkey.—It is reported that several cases of cholera have appeared along the Bosphorus, following the severe floods which have caused great distress among the Turks.

Radium Trust.—Reports of the continued rise in the price of radium have been followed by the statement that a corporation is to be formed in London for the purpose of controlling the entire supply of radium now in existence and also the total future production. The Archduke Ferdinand of Austria and the Hungarian National Bank are said to be interested in the company, which is to be known as "European Radium, Limited."

Medical Colleges Open.—The fifty-ninth annual session of the Atlanta Medical College, Atlanta, Ga., opened on September 29 with the prospect of the heaviest registration in years.

The State Medical College of Galveston, Texas, opened on October 1, Dr. J. P. Simonds, professor of preventive medicine, addressing the students.

Prof. Earle B. Phelps has resigned from the Faculty of the Massachusetts Institute of Technology and from the staff of the Sanitary Research Laboratory in that institution to accept a position as professor of chemistry at the United States Hygienic Laboratory, U. S. Public Health Service, Washington, D. C. Professor Phelps has been in charge of extensive investigations carried on during recent years at the Institute on the purification of water and sewage and allied subjects, has acted as consulting sanitary engineer to many of the largest cities of the United States, was recently appointed a member of the New York State Commission on Ventilation, and is well known as a contributor to the various technical journals along the lines of sanitary chemistry, bacteriology, and engineering. His work at the hygienic laboratory will be largely a continuation of his various activities elsewhere, and will be devoted especially to investigations of the pollution of interstate streams which the Public Health Service is now undertaking.

Personals.—Dr. Harry Burnett Burns of Pittsburgh, Pa., has been appointed acting director of the Department of Public Health of Pittsburgh, to fill out the term of Dr. E. R. Walters, resigned.

Dr. Elliott Washburn of Taunton, Mass., has been made superintendent of the Massachusetts State Sanatorium for tuberculosis, at Rutland, succeeding Dr. P. Challis Bartlett.

Dr. Maurice McD. Seymour of Regina, Saskatchewan, was, on September 20, elected president of the Canadian Public Health Association.

Dr. Charles Wood McMurty announces that after October 1 he will be associated in practice with Dr. Charles Townshend Dade, at 25 West Fiftieth street, New York.

Dr. Colman W. Cutler of New York announces his removal to 24 East Forty-eighth street.

Dr. William Bradbury Noyes has removed to 221 West Fifty-seventh street, New York.

Dr. Alfred J. Brown has removed to 156 East Sixty-fourth street, New York.

Dr. Alfred F. Hess announces his removal to 16 West Eighty-sixth street, New York.

Dr. Samuel G. Dixon, State Commissioner of Health and Charities of Pennsylvania, was successfully operated on for abdominal abscess by Dr. John B. Deaver, at the University Hospital, Philadelphia, on October 3.

Charitable Gifts.—St. Joseph's Hospital, Yonkers, N. Y., has received from Mr. A. S. Cochran of that city a gift of $25,000 toward a fund for the enlargement of the hospital. A campaign to raise an additional $85,000 by public subscription has been begun.

Mrs. John W. Minturn, who died recently in New York, widow of the founder of the Hospital for Scarlet Fever and Diphtheria Patients, formerly known as the Minturn Hospital, left a bequest to the hospital of $15,000.

Dr. Adolph Schmidt of the University of Halle, who is to deliver the Harvey Lecture on October 18, will lecture at the New York Post-Graduate School on chronic pancreatitis on October 21 at 4 P. M. The members of the profession are invited to attend.

A Decision against the Plan of Organization of the American Medical Association.—In the case of Dr. G. Frank Lydston against the State's Attorney of Cook County, Ill., in mandamus to compel service of quo warranto writs on the Trustees of the American Medical Association, the Appellate Court handed down an opinion on October 9 that the A. M. A. is holding meetings contrary to law, that its election and delegate system are illegal, and that every member of the Association is entitled to a direct vote. Unless the Supreme Court reverses this decision it may necessitate a complete reorganization of the Association. Dr. Sanders of Montgomery, Ala., argued to the same effect several years ago, in a series of letters to the MEDICAL RECORD, but he failed to convince the members that the reorganization of the Association had not been legally effected.

Medical Society of Cape May County, N. J.—At the annual meeting held on October 7, the following officers were elected for the ensuing year: *President,* Dr. Charles W. Way, Dennisville; *Vice-President,* Dr. E. Physic, Cape May; *Secretary,* Dr. Eugene Way, Dennisville; *Treasurer,* Dr. H. H. Tomlin, Wildwood.

Surgical Congress.—The Clinical Congress of Surgeons of North America will convene in Chicago on November 10, and will be formally opened on the evening of that day, when the Presidential Meeting will be held in Orchestra Hall. At this meeting the President-elect, Dr. George Emerson Brewer of New York, will be inaugurated and will deliver the annual address. The presidents of the American Medical Association and the Canadian Medical Association are expected to be present at this meeting and to deliver brief addresses. On November 13 there will be held a cancer symposium at which the cancer problem will be discussed by prominent surgeons and laymen representing various organizations.

Utah State Medical Association.—The annual meeting of this society was held in Salt Lake City on September 23 to 25, the following officers being elected for the ensuing year: *President,* Dr. John F. Critchlow, Salt Lake City; *Vice-Presidents,* Dr. Joseph R. Morrell, Ogden; Dr. Heber E. Robinson, American Fork, and Dr. Margaret A. Freece, Salina; *Secretary,* Dr. W. Brown Ewing, Salt Lake City; *Treasurer,* Dr. H. P. Kirtley, Salt Lake City.

Association of Railway Surgeons.—The twenty-third annual session of the New York and New England Association of Railway Surgeons will be held at the Hotel Astor, New York, on Wednesday, October 22, 1913, under the presidency of Dr. John W. LeSeur of Batavia, N. Y.

Southern Medical Association.—The annual

meeting of this association, of which Dr. F. A. Jones of Memphis, Tenn., is the president, will be held at Lexington, Ky., on November 18 to 20.

The Norwegian Hospital Association.—On Wednesday, October 8, 1913, the regular meeting of this association was held in the directors' room of the hospital. Dr. G. H. V. Hunter read a paper on "Sex Determination"; Dr. C. E. Lack spoke about "Percentage Infant Feeding"; Dr. Fisher read a report on "Pathology," and Dr. R. E. Coughlin paid a personal tribute to the late Dr. Henry Cushman Turner, founder and dean of the hospital medical staff. This Association was organized fifteen years ago, this being the first meeting held in the hospital building. The officers are: Dr. Robert G. Moore, *President;* Dr. Louis Stork, *Vice-President;* Dr. Henry Spelman, *Secretary and Treasurer.*

Concerning Death Certificates.—The Commissioner of Health of New York City has issued a circular letter to physicians in the city requesting their cooperation in the matter of reforming the procedure as to furnishing blank forms of certificates of death. For many years and until quite recently, blank certificate forms were given to undertakers, who as it became necessary took the certificates to the physician for signature, but the department now intends to break up this practice. As the law holds the physician responsible for the filing of the certificate of death within thirty-six hours after its occurrence, it will be necessary for the physician to notify the office of the borough in which he practises that he needs such blank forms, and these will then be sent to him as soon as practicable.

Obituary Notes.—Dr. George M. Grace of Graceville, Fla., a graduate of the Atlanta Medical College, Atlanta, Ga., in 1881, was struck by a railroad train on September 28, and instantly killed, in the sixty-second year of his age.

Dr. Erastus M. Drollinger of South Bend, Ind., a graduate of the Eclectic Medical College, Cincinnati, O., in 1878, died at his home, on October 2, aged 60 years.

Dr. Ephraim Wood Norwood of Spencer, Mass., a graduate of the Harvard Medical School in 1882, and a member of the American Medical Association and the Massachusetts State and Worcester County Medical Societies, died at his home on September 11, aged 67 years.

Dr. Charles Eugene Michel of St. Louis, Mo., a graduate of the Medical College of the State of South Carolina, Charleston, in 1857, and a surgeon in the Confederate Army during the Civil War, died at his home on September 29, aged 80 years.

Dr. George S. Brown of Birmingham, Ala., a graduate of the Jefferson Medical College, Philadelphia, in 1885, and a member of the Southern Surgical and Gynecological Association, died in the Lakeside Hospital, Cleveland, O., following an operation for gallstones, on September 27, aged 54 years.

Dr. Thomas Jacob Biggs of Stamford, Conn., a graduate of the Medical College of Ohio, Cincinnati, in 1887, formerly an assistant surgeon in the United States Army, a member of the American Medical Association and the Connecticut State and Fairfield County Medical Societies, and health officer of the city of Stamford since 1909, died in the Somerset Hospital, Somerville, N. J., from disease of the kidney, on October 10, aged 48 years.

Correspondence.

THE TREATMENT OF CANCER.

To the Editor of the Medical Record:

Sir:—The editorial on "The Curability of Cancer" appearing in the Medical Record of September 20 is most opportune and justly characterizes the pessimistic attitude of the mass of medical men towards non-operative cures as likely to kill incentive and discourage the search for curative measures. One cannot but join the writer in wondering if those who so stoutly urge the knife as the only remedy read the numerous articles in the journals giving proof of cures by other methods. It is possible that these writers do not read medical literature not directly connected with their chosen daily occupation. Yet, some of these stalwart preachments of early operation have a worthier source and are designed to combat that form of pessimism havings its origin in an ill-defined belief that cancer is not local, even in its inception. I have been astonished to find how prevalent this view is, even among surgeons dealing occasionally with the disease. No real worker in malignant affections denies the purely local character of incipient cancerous growths, hence it follows that in this stage they may be removed surgically when accessible. The surgeon seriously interested in the subject also sees failure under radiation methods undertaken in cases that could have been extirpated, the patient having meanwhile lived under the daily possibility of an incurable metastasis to internal organs. The radiologist, on the other hand, sees even more instances where attempted removal by excision has resulted in local reimplantations that present greater therapeutic problems than the original growth.

A clear view of our own and of our neighbor's duty in these apparently conflicting experiences will come only with an active, practical realization that malignant disease must be due to a foreign organism, and by adjusting our work to fit this view in advance of its classical demonstration in research. Why should not this be done? It will not be the only instance in which the etiological relations of germs to disease have been practically assumed in advance of their laboratory isolation. And I may say, in passing, that the discovery and final demonstration of an endocellular bacterium as the cause of cancer in the daisy plant by Dr. Erwin F. Smith, of the Bureau of Plant Industry at Washington (Vide Bulletin No. 255, Bureau of Plant Industry of the Department of Agriculture), bring the discovery of similar human cell-stimulating organisms measurably close.

That even an unusually distinguished surgeon may subconsciously look at this matter both ways was evident recently when, in private conversation, he replied to the question of his belief or disbelief in the germ origin of cancer that he unquestionably regarded it as a germ disease; yet, a few months later he made remarks in a public discussion that could only be interpreted as an offhand revelation of a mental attitude that regarded the disease as an intrinsic degeneration. It is true that a degeneration may be due to an infective agent. My objection to the term in connection with cancer is that it lacks a forceful expression of autogenesis and even suggests a transmutation of species, such as is involved in the idea that one kind of tumor can turn into another except by conquest and replacement.

If we assume, as urged in this letter, that it is wise to anticipate in practice a part at least of the practical value resulting from the hoped-for demonstration of the nature of cancer, all our efforts should be dominated by the corresponding precautions. These involve three important facts:

1. A malignant growth that is capable of being excised entire and without being wounded permits the host to be practically and permanently cured in this manner.

2. Malignant growths, being composed of living cell parasites that depend on the host cell for pabulum, are readily stimulated to quickened growth by anything that increases the vital activities of their environment, such as incomplete operations or irritations of any kind. They, in fact, grow fastest in the young and in the vigorous. Autoinfection is also one of the most prominent clinical facts in malignant diseases, metastases being instances, among others, of this phenomenon. As a consequence infected living cells that may be exposed or loosened in an excision operation may reimplant themselves in the fresh wound if allowed to come in contact with it.

3. Modern medicine does not justify the assumption that physical removal of cells or organs infected with a parasite is the only way to rid the body of the parasite. The brilliant results of modern chemotherapy, as well as the older use of quinine to destroy the malarial plasmodium, forbid such a generalization as to cancer, and stimulate us to employ radiant energy, electrochemical therapy, and any other means to destroy the germs *in situ* when this course is indicated.

The wisest correlation of our curative efforts would therefore be as follows: Epitheliomas and other forms of malignant growths which rarely or never give rise to metastases should be placed under one or other of the germ-killing forces, such as ionization, fulguration, or radiation. If these usually better, simpler, and more cosmetic methods are not available the excision should be complete and without attendant risk of operative reinfection of the wound.

Carcinomas, which at any moment may lead to internal daughter tumors or metastases, if operable, should not be subjected to these chances by the employment of any of the radiation forces over the long periods of time usually required for their effective action. But, operability by incision should be defined rigidly as a capability of being removed entire and unwounded. If inoperable in this sense there is still a chance of operability by the electrochemical method of bipolar ionic destruction, which is the latest modification of the method of which almost the earliest announcement was made in the MEDICAL RECORD of July 31, 1897, by the writer. The particular advantage of the bipolar modification is the shortening of the time of operation to about thirty minutes and a considerable extension of the field of the method in the more desperate cases. By it all germ life of the cellular mass is killed *in situ* and bloodlessly, thus considerably enlarging the field of possible surgical intervention. The fulguration method of deKeating Hart, which follows incomplete operation, is also a resource of value. When all operative methods are contraindicated by one or other reason some form of radiotherapy should be employed and pushed to the limit dictated by experience.

Similar considerations should govern the treatment of sarcoma, except that radiotherapy by the Roentgen rays and by radium have a more equal elective value with positive surgical procedures, and in some varieties we may employ the Coley serum as a last resort.

G. BETTON MASSEY, M.D
1831 CHESTNUT STREET, PHILADELPHIA.

OUR LONDON LETTER

(From Our Regular Correspondent.)

THE PANEL SYSTEM; COMPLAINTS OF PATIENTS, SURPLUS FUND, EXTRAORDINARY CLAIM—ANTITYPHOID INOCULATION—REMEDIES FOR PAIN AND SLEEPLESSNESS—DR. ALBEE'S OPERATION.

LONDON, September 26, 1913.

THE panel system controversy becomes more and more acute and even embittered. "Panel or non-panel," that is the question as to individuals, and it threatens to divide the profession, if not permanently, at least, for a long time, into hostile camps. The panel doctors affect to disregard the opinion of the non-panel, who in their turn look down upon those who, they say, after protesting vigorously that they never would, soon retracted their assertions and rushed panic-stricken into the official fold. The public seems to take a languid interest in the matter and regard the panel as an inferior practitioner, as they used to do the parish doctor. There have been complaints made against panel practitioners by their insured patients and so much talk of them that the committee has inquired into and reported upon them. It seems that thirty-eight formal complaints were made, and the report states that twenty were substantiated —not a great proportion, considering the enormous number of patients, many of them ignorant and exacting. In all but two the complainants were merely advised to transfer their names to another list. Of the two exceptions one doctor proved to be insane and the other had withdrawn from the panel. A much more important question has been raised concerning a large sum of money. You will remember that the panel doctors were to have a fixed sum for every patient on their list. This has been paid. Money was assigned by Parliament to meet the case of every person insured under the act. But a large number declined to avail themselves of the panel doctor and many were otherwise not in need of being on his list (hospital and other patients). Consequently the committee had a large surplus (over £100,000) after paying all the sums due to the panel doctors. To whom does that surplus belong? It would seem, to the state, which had provided it. To the astonishment of most people the panel doctors set up a claim for it, pretending that it was intended for the medical service of the state, and as they only had done that service it ought to be divided between them. The committee hesitated. After some discussion counsel's opinion has been obtained. It is that "the committee is not entitled to make presents or distribute largess among the panel doctors." In response to another question counsel wrote: "I think the committee cannot, as matters stand, deal with the fund." Notwithstanding this, the panel men are not satisfied, and yesterday Dr. Mills represented them to the committee, arguing that the fund belonged to the medical profession. A number of the committee replied that it would shock the public conscience that a payment should be made to doctors on the panel when they had not done a single stroke

of work in connection with it. The non-panel doctors are already pointing to this demand as something degrading the whole profession.

Antityphoid inoculation has attracted a little more attention here since it was discussed at the Congress, when naval and military medical officers of France and Italy, where it has been more extensively used, related their experiences. Major Russell (U. S. A.) stated what had been done in your army, and Sir W. Leishman reported the work in the R. A. M. C. The French army surgeons have given a full trial to Professor H. Vincent's polyvalent vaccine in Algeria, Morocco and Tunis, as well as among the home troops. The operation has been voluntary, but from an early period it became popular. Professor Vincent, who came to the Congress, was able to report that the method had been employed for the first time in civil practice during an epidemic in two French towns, in which 700 persons submitted to inoculation, and not one of them was attacked by the fever. The vaccine he employs is said to contain 400,000,000 bacilli per c.c. No antiseptic is added, but it is sterilized by ether, which evaporates before use. Sir W. Leishman said that in the R. A. M. C. a monovalent vaccine had been used and two doses were given, one containing 500,000,000 dead typhoid bacteria. The second had twice as many and was given after an interval of ten days. There was very little reaction. Iodine has been used by MM. Ravigne and Sénez to sterilize the vaccine, and many successful results reported. The impression at the Congress seemed to be that inoculation was a most valuable preventive, and all the methods were successful if carried out with care, as they had been.

Early this year MM. Louis & Combe, surgeons in the French army, who had also worked on the subject in M. Vincent's laboratory, contributed to the *Monde Médical* their experience of 8,000 inoculations. They urge a resort to injection wherever there is any likelihood of coming in contact with the germs. It is applicable, they say, at any age after three years, and children bear the treatment remarkably well. The mildness of the operation and its simple technique bring it within the scope of every practitioner. What, then, may be the contraindications? MM. Louis & Combe lay stress on these: In every case antityphoid vaccination is only to be performed on perfectly healthy persons. This requirement would seem to exclude the consideration of every form of disease, but they go on to particularize as special contraindications all acute affections and most chronic ones while running their ordinary course. Tuberculosis if latent may be lighted up, and in case of doubt the soil should first be tested with a minimum dose, the temperature being taken, and if the reaction occur the treatment discontinued. Malarial subjects may be treated during the intervals if preceded by a dose of quinine. Syphilitics without active symptoms may be inoculated. But these if cachectic, or, indeed, any such suffering from kidney or heart disease, must not be injected. As much may be said of all debilitated persons, as, in fact, was implied in the first-named requirement of perfect health. They report that 27,000 persons have to their knowledge been inoculated, and not one has had symptoms of typhoid fever. They quote in support the physician to St. Louis Hospital at Meknes to the effect that the typhoid "wards, not long ago crowded, are nearly empty: out of 4,000 soldiers we have only two being treated for typhoid; it is marvellous."

Pain is so frequent a cause of sleeplessness that the two are not uncommonly spoken of as if they were one, or at least seldom separated. The remedies for one are also effective in some degree for the other, and in turn get discussed together. This sometimes leads to a little confusion, as it seemed to do in a discussion at the International Medical Congress entitled "The Action and Use of Remedies for Pain and Sleeplessness (Excluding Anesthetics, Local and General)." In opening it Professor Cushing laid down the properties which he considered constituted an ideal soporific. These he said were (1) that it should only act on the seat of disturbance—viz., the higher cerebral centres; (2) should act regularly; (3) not be repugnant in taste or odor and not poisonous. The sulphonal group he considered uncertain and sometimes dangerous. Chloral had been thought to depress the heart, but he found no evidence that it had any effect of the kind. He placed it and veronal at the head of hypnotics. Paraldehyde was less reliable and had a disagreeable taste and smell. As to pain, he had little to say, as there seemed nothing new since the substitution of morphine for opium, though drugs of the salicylic or phenacetin type might be named as useful in neuralgia and headaches.

Dr. Robert Jones, regarding the case of insane patients, held that the great thing was to break the habit of sleeplessness by removing the cause—an excellent prescription for sane people also. Though he reviewed a large number of drugs, he also dwelt on other measures, such as removing high tension, cardiac disturbance or failure, and other causes, mental and moral, as well as physical. Prof. R. B. Wild spoke of analgesics in incurable disease when morphine was most useful to meet pain. Of non-narcotics he found phenacetin and acetosalicylic acid of great value.

Prof. Bradbury found veronal effectual—so much so that often in his experience it was necessary to repeat it only at some three days' interval. He disliked sulphonal.

Among a number of other statements and remarks in this discussion I may note that Professor Dixon claimed that he first observed that the indifferent hypnotics increased the cerebrospinal fluid. Further, he and Dr. Halliburton showed that drugs introduced into the upper part of the spinal canal were absorbed and produced their effects as rapidly as if injected into a vein. Dr. Fortescue-Bricklade examined soporifics and anodynes from the chemical point of view as influencing their therapeutical action.

Professor Baruch advocated more instruction in the schools and universities on hydrotherapy. Dr. Roch ascribed better effects to combinations of soporifics, *e. g.* morphine with heroin, veronal with codeine, antipyrin with pyramidon. Dr. Garron had seen untoward effects from a small dose of heroin and morphine. Mineral waters, climate and other measures apart from drugs were referred to, and then some demonstrations were given in the subsection of pharmacology held at University College.

Dr. F. H. Albee during the International Medical Congress performed his osteoplastic operation for Potts' disease at the Royal National Orthopedic Hospital. He used his electric circular saw. The patient was one of Mr. Muirhead Little's, senior surgeon to the hospital, a son of the late Dr. W. J. Little, to whom orthopedy owes so much. The patient is going on very well.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

APHTHOUS FEVER—VACCINE TREATMENT OF TYPHOID FEVER—NECROLOGY: PROFESSOR JACCOUD; THÉOPHILE ANGER; MEDICAL INSPECTOR GAUJOT.

PARIS, August 23, 1913.

APHTHOUS fever was the subject of a paper read by Cadiot before the Academy of Medicine. The possibility of the transmission of this condition to human beings, which has been questioned by a majority of physicians and veterinarians, is to-day almost universally admitted. There are records of over 1,500 cases of the transmission of aphthous fever from animals to man. In 1902 the Academy of Medicine passed a resolution calling upon the sanitary authorities to prohibit the sale of milk obtained from cattle suffering from aphthous fever, unless the milk had been boiled or pasteurized at 85° Centigrade.

Galippe insists upon the importance of the inherited or acquired constitutional condition of the subject with reference to his susceptibility to aphthous fever. Many cases of aphthous stomatitis are certainly nonspecific in character.

"The Vaccine Treatment of Typhoid Fever" was the title of a paper read by M. Chantemesse. Roux was the first to suggest this method of treatment twenty-five years ago. This form of therapy is undoubtedly a good one provided that the following rules are followed: The treatment should be employed as soon as possible after the beginning of the disease. Small doses of sterilized typhoid cultures should be used. Only two or three injections should be given at intervals of several days. Only the most minute doses should be employed in the case of patients severely ill, or in whom the treatment is begun late, on account of the anaphylaxis that develops in the courses of typhoid fever. The bactericidal power of the vaccine causes the entrance into the circulation of a large dose of toxin which gives rise to a defensive reaction on the part of the lymphoid apparatus. It is this reaction which increases the resistance of the patient and facilitates cure. Of 1,000 typhoid fever patients treated by M. Chantemesse with his serum there were but forty-three fatalities, while at the same time in the other hospitals of Paris there were 170 deaths in 1,000 cases. Roux believes that antityphoid vaccination provides an excellent means of diminishing the mortality from typhoid fever.

The vaccine of Chantemesse consists of an emulsion of typhoid bacilli killed by heat. It is prepared in the following manner: Upon a gelatin plate well spread out there are sown five cubic centimeters of a 24-hour-old bouillon culture of typhoid bacilli. The plates are kept in the incubator at a temperature of 57° C. for eighteen hours, at the end of which time there are added to each plate 5 cubic centimeters of sterile physiological salt solution. The culture is detached from the surface of the gelatine by shaking. The contents of several plates are then emptied into a sterile flask, thoroughly stirred, and then divided into sterile test-tubes, which are sealed with the aid of heat. One definite volume of the emulsion is diluted with one volume of water containing formaldehyde and colored blue. The sealed tubes are heated in the water bath and kept at a temperature of 56° C. for one hour during which period they are shaken several times. The vaccine should be used not later than three months after its preparation. Chantemesse's vaccine consists of an emulsion of the bodies of the typhoid bacillus suspended in a sterile liquid. The antityphoid vaccines prepared by Professor Vincent of Val de Grace consist in the one case of an emulsion of the typhoid bacilli killed by ether, and in the other case of an autolysate of the typhoid bacilli sterilized by ether. The Academy of Medicine approves and authorizes the preparation of the vaccines of Chantemesse and Vincent.

Professor Jaccoud, permanent secretary of the Academy of Medicine of Paris, has recently died. He was one of the most striking figures in the medical world during the latter half of the nineteenth century. His eloquence and remarkable memory helped to make him famous. Born at Geneva in 1830, Jaccoud met with many difficulties in the early part of his career. While he studied all day at the hospital, or in the medical school, he played the violin at night at the Opera Comique. He became an externe in 1854 and an interne the following year. In 1859 he received the gold medal of the Hospitals, and in 1860 defended a remarkable thesis on the pathogenesis of albuminaria. In 1862 he became physician to the hospitals of Paris and in 1863 assistant professor in the medical faculty. As professor of clinical medicine his success was established. His deep erudition was associated with an extraordinary memory. He accomplished a great amount of work. He carried alone to completion the "Dictionary of Practical Medicine and Surgery," a work which will remain a monument to its creator.

Théophile Anger has just died at the age of 77 years. He had been the favorite pupil of Nélaton, who had him appointed to the staff of the Emperor Napoleon III during the war of 1870. After the battle of Sedan he returned to Paris where he was put in charge of the Hertford Ambulance which had been established by Sir Richard Wallace. In 1871 he received the appointment of surgeon to the hospitals of Paris and then began the most brilliant part of his surgical career. Anger published interesting books on cancer of the tongue, and on auto plastic operation for the relief of epispadias and hypospadias. In 1882 a failure in health compelled him to give up his work for a long time. An accident deprived him of the use of his right arm, so that he could not operate without difficulty. His pupils became his assistants and collaborators.

Medical Inspector Gaujot has recently died at the age of 86 years. He was one of the oldest and most esteemed members of the Surgical Society. Interne in 1851, he was successively instructor of operative supply and clinical surgery at Val de Grace, and later was made director of the School of Applied Studies at Val de Grace. As army surgeon he had an active service during the wars in Italy and in 1870. His principal work was the "Arsenal of Contemporary Surgery." This work is an important document in the history of surgery in the pre-antiseptic days.

Hereditary Brachydactylia.—J. Drey reports the case of a family in which for five generations this condition was observed in a number of individuals, some of whom had defects in the terminal phalanges combined with ankyloses of the terminal joints, and some of whom had only one of these deformities. A direct heredity was perceived in the last three generations.—*Zeitschrift für Kinderheilkunde.*

Progress of Medical Science.

1. Indications for the Relative Values of Tonsillotomy and Tonsillectomy. J. L. Goodale.
2. Remarks on the Rational Treatment of Genitourinary Tuberculosis. R. F. O'Neil and J. B. Hawes, 2d.
3. Observations on a Series of Ninety-eight Consecutive Operations for Chronic Appendicitus. E. A. Codman.
4. A Case of Infection with Nocardia. A. E. Steele and R. I. Lee.
5. One the Relief of Earache and Induction of Operative Anesthesia by Infiltration of the Auriculotemporal and Tympanic (Jacobson's) Nerves. P. C. Skillern, Jr.

1. **Tonsillotomy versus Tonsillectomy.**—J. L. Goodale concludes that it has not been demonstrated that complete removal of the tonsils is followed by harmful effect upon the general system. Tonsillotomy involves usually less trauma than does tonsillectomy, but in the latter the method of removal is of primary importance, a sharp dissection down to the tonsillar artery, with snaring of the vessels giving the least amount of inflammatory reaction. Of the two operations tonsillectomy shows a larger percentage of septic complications, due both to the greater trauma usually occasioned, and also to the relatively larger number of septic conditions where of late years an operation is undertaken. The relative frequency of postoperative hemorrhage is not definitely established, but in view of the available methods of treatment it is no longer a serious complication if dependent upon local causes. While gross deformities of the parts involved are not likely to follow tonsillotomy, yet cicatricial occlusion of the lacunar orifices is frequent, and may lead to an intensification of the original chronic inflammation. The indications for operation should be determined by the pathological changes of the tonsils, which are actually a detriment to the individual. Simple hyperplasia, if obstructive or favoring catarrhal conditions, and if persistent, may be sufficiently treated by a tonsillotomy, especially in children. The systemic ill effects of chronic tonsillitis may be increased by a tonsillotomy. Complete removal is here preferable to a partial one, although mild cases of chronic inflammation may be sufficiently relieved by appropriate treatment without excision. Infection of the fauces due to virulent microorganisms may not be prevented by removal of the tonsils. Recurrent local infections or general infections having their origin in the tonsils require tonsillectomy as soon as a favorable moment for operating arrives. Tonsillotomy may be expected here to prove inadequate. Recurrent acute catarrhal infections of the throat require complete removal of the tonsils if these show chronic inflammation, although immunity against subsequent attacks is not necessarily secured. Local tuberculosis of the tonsil requires complete removal of the organ. In young children with adenoid enlargement requiring removal the tonsils should not be excised unless demonstrably causing injury or favoring attacks of acute middle ear inflammation. If an impairment of the speaking voice is dependent upon tonsillar disturbances, these may be corrected according to the principles already given, and if a tonsillectomy is indicated, it may with proper technic be performed without anxiety. In singers slight alteration in the tension of the palatal muscles may influence the voice either favorably or unfavorably. In the case of beginners with harmful alterations of the tonsils a partial or complete removal may usually be done, if the local or general welfare of the patient demands it. With increasing length of singing experience a correspondingly conservative attitude should be maintained, particularly in respect to truly fine voices.

3. **Operations for Chronic Appendicitis.**—E. A. Codman records his observations in a series of ninety-eight consecutive operations for chronic appendicitis. All cases operated upon were diagnosed as chronic appendicitis, but only sixty-one appendices had demonstrable evidences of having been inflamed. In seventeen cases the real causes of the symptoms as determined after operation were probably as follows: Chronic salpingitis, 2 cases; tuberculous mesenteric glands, 3 cases; painful right inguinal hernia, 1 case; gallstones, 2 cases; small ovarian cyst, 1 case; tuberculous peritonitis, 1 case; congenital pelvic kidney, 1 case; tapeworm, 1 case; cardiospasm, 1 case; megasigmoid, 1 case; ptosis and megaduodenum, 1 case; appendix abscess, 1 case; general syphilis, 1 case. But six of these seventeen cases also happened to have a chronic appendix. There were two fairly distinct symptom complexes. (*a*) The true appendix sequence. Cases which have had a number of previous attacks lasting a few days—not hours. These attacks are characterized by epigastric or general abdominal onset and right iliac localization of pain followed by gradually subsiding tenderness after the pain has gone. In the interval between the attacks tenderness at McBurney's point may be absent. These cases seldom have habitual constipation. They show definite appendix strictures, obliteration, or adhesions. (*b*) The pseudoappendix sequence. These cases have right-sided pain in the appendix region which is frequent, usually daily, though intermittent. There is general right-sided tenderness, especially at and about McBurney's point. They have no long interval of freedom. The attacks are mild and not often feverish. They are constipated and usually have the other stigmata of visceral ptosis. In the sixty-one definite appendix cases constipation, usually not habitual, was present in only twenty-one cases, and in eight of these mobile ceci were also present. But in four cases no note was made. In the thirty-seven cases with normal appendices sixteen were habitually constipated. Diarrhea, persistent or intermittent, occurred in only nine cases out of eighty-seven recorded, and can no longer be quoted as a symptom of chronic appendicitis, but when present in a doubtful case is in favor of a diseased appendix, because eight of the nine were among the sixty-one true chronic appendices. One of the things that interested the author most, was that dyspeptic symptoms, especially the hyperacidity form which are now considered the cardinal symptom of duodenal ulcer, were found at all severe in only twelve cases and were vaguely present in only twenty-five more.

1. **The Chetwood Operation for Retention of Urine.**—E. L. Keyes, Jr., states that during the past ten years he has employed the Chetwood operation upon about one-quarter of his cases of prostatic hypertrophy. He has also employed it for the removal of all minor obstructions, such as bars and contractures at the bladder neck, when simple perineal section seemed likely to prove inadequate to afford proper drainage for the bladder. Among the fifty-seven patients operated upon, twenty-seven have been followed for a year or more (omitting cases of carcinoma, tabes, and tuberculosis). Seventeen, or sixty-three per cent., of these patients were cured, and the cures verified for nine years in one case; seven years in three cases; six years in one case; five years in one case; four years in two cases; three years in four cases; two years in one case; and one year in three cases. Three patients have grave incontinence of urine; two incomplete and one

complete. Seven patients were incompletely relieved, and of these two went as long as five years before their symptoms again gravely inconvenienced them. The general aspect of these statistics is not particularly good; for although the mortality is low, the proportion of the absolute cures is also low. But the author believes that the average result is far better than he could have obtained by any other operation. A number of them were desperate risks, and most of them represented that class of prostate that is too small to be satisfactorily dealt with by prostatectomy.

7. Early Diagnosis of Cancer of the Uterus.—R. B. Hall enumerates the early symptoms of cancer of the cervix, in the order of their importance, as follows: (1) a watery discharge; (2) an irritable bladder; (3) a little irregular bleeding, and (4) a disagreeable odor. In reference to the watery discharge, he does not mean the ordinary leucorrheal discharge that women frequently complain of, but a watery discharge not unlike beef brine in its appearance. It may not be very profuse, but it is enough to stain the linen brownish. It irritates the vulva. It is more or less constant for a varying period of from five or six weeks to three or four months, before the patient considers herself ill. This is a most important symptom. Slight irregular bleeding should be immediately investigated, but it is not especially an early symptom. Hemorrhage and pain come late in the disease. Cancer of the cervix should be differentiated early from erosion, laceration with inflammation, cystic degeneration, tuberculous ulcer, and chancre. If malignant disease is present a small nodule is to be found. As regards the first three, no examination will be complete without the aid of the microscope. Tuberculous ulcer and chancre are rare and there should be no very great difficulty in their diagnosis. The early diagnosis of cancer of the body of the uterus is also much neglected. Its approach is insidious and, unlike cervical cancer, it may occur in the maiden as well as in the woman who has borne children. It is comparatively rare before the menopause and the earliest symptom is a watery discharge with slight irregular hemorrhage gradually increasing, and pruritus. Pain comes on later in the disease when the uterus has become enlarged by the new growth and is endeavoring to rid itself of the foreign body. The diagnosis of cancer of the body of the uterus is not at all difficult with the clinical history. The physician will find the uterus enlarged, freely movable, and more sensitive than normal, with no perceptible disease of the cervix. In advanced cases a probe gently introduced may show a depth of three inches or more and cause a discharge of bright red blood. If the first examination does not give a positive diagnosis the uterus should be curetted under an anesthetic and microscopic examination of the scrapings made. Only rarely has the author had to make a secondary curetting.

8. Cancer of Cervix Uteri.—E. Ries states that in the beginning when there is no cancer in the body except at the original focus one ought theoretically at least to cure by its removal *en bloc*. In the later stages much wider limits must be given and one must include in the cancer block all the lymph vessels between the original focus and the metastatic foci in adjoining lymph-nodes. One must consider risks of leaving behind infected portions or wandering cancer cells in still uninvolved lymph channels. The observation of these at a distance, however, i. e., of carcinoma in transit, is practically unknown. The improvement in results of operations for cancer in any part of the body can be shown to depend on the continuous rather than the discontinuous dissection out of the morbid growth. Where the dissection is discontinuous the results are most unsatisfactory. The operation for cancer of the cervix involves greater risks than that of cancer of some other portions of the body, that of the breast for example. The accessory risks from anesthetic or infection carried in from the outside are the same in carcinoma of the cervix as in other cancer operations. The gravest accessory risk is that of sepsis from the infected primary tumor by the much-dreaded tearing of the cervix or infection of the field from crumbling lymph-nodes, which, in addition to the carcinoma, have been loaded with virulent germs from the primary focus. The author has little doubt that virulent germs may lurk not only in suppurating lymph-nodes, but in lymph-vessels in their neighborhood as well. The enlargement of the block to the limits indicated by the author in 1895 has greatly improved the remote results, but at the cost of increased inherent risks from hemorrhage, injury to ureters, and large wounds in the connective tissue. The dissection of the ureters out of the broad ligaments unavoidably breaks the rule of continuous dissection, and this is another point of weakness. It could be eliminated if one could include the ureters in the carcinomatous block and resect them every time, but there is a limit to the tolerance of the patient and also of the operator. The operation for cervical cancer is the most extensive he knows of in surgery and there is no means of which he is aware by which one can determine the limits of this tolerance in individual cases.

12. **Paresis.**—C. F. Ball notes the recent general acceptance of the specific origin of paresis and the changes of opinion regarding so-called parasyphilis generally, and asks how far back toward the primary infection one should date the disease. Together with this question arises the other, whether active and persistent specific treatment when the symptoms first appear would favorably influence the latter course. During the past two years the author has made Wassermann tests of the blood in all his hospital patients, and if there were nervous symptoms with a positive Wassermann, lumbar puncture was made and three reactions tested. With the modern methods diagnosis is greatly facilitated. He quotes Nonne and Schüle as to the positive cure of paresis with seeming approval, but admits that possible relapses should always be reckoned with in giving a prognosis of apparent cure. For two years he has used injections of sodium nucleinate in his paretic patients, and gives particulars of some cases. He says he cannot claim very great success with it, but it seemed to exert a favorable influence in all but two.

1. **Failure of Lactation.**—H. C. Cameron notes that it may be asked why the infant should be born before the flow of milk is established, and why it should be left to the child to secure a sufficient supply by its own exertions. He believes that one may see in this a very complete and successful provision against the danger of overfeeding the child. When the child has a good appetite, sucks well, and empties the breast completely the amount of milk secreted increases with each nursing. There is here a wonderful adaptation of supply and demand. It is true to say that the child grows in strength and size because there is an increasing flow of milk; it is equally true to say that more milk is secreted because the child grows in strength and power of suction. But let some accident diminish his appetite for a few days—some slight pyrexial disorder, for example, or a trifling dyspepsia—then with diminished suction less milk is secreted, and the infant involuntarily imposes upon himself a period of partial starvation.

3. **The Bacillus of Leprosy.**—H. Fraser and W. Fletcher state that material for purposes of cultivation on various media has now been obtained from 32 non-ulcerating nodular cases of leprosy and 373 inoculations made on the various culture media. It is curious, in view of the findings of other investigators, that they have consistently failed to obtain a culture of the bacillus lepræ. There can be no doubt but that material swarming with bacilli has been employed on each occasion. This was clearly demonstrated by the microscopical examinations which were made in every case. From the examinations made of nodules which have been incubated on culture media for periods ranging from a few days to nine months, no evidence has been obtained that the bacilli had increased or lessened in number. Those investigators who have recorded an increase in the number of organisms as a result of microscopical examination must surely have failed to observe the bacterial richness of the material employed for inoculation. Anyone who has examined smears prepared from freshly excised leper tissues must be struck with the enormous masses of acid-fast bacilli present, and we are unable to comprehend how it is possible to state in a case where no macroscopic growth is apparent that an increase, recognizable only by the microscope, has occurred.

4. **The Pathology of Parasyphilis.**—J. McIntosh and P. Fildes, in summing up their concept of syphilis of the central nervous system, hold that it consists of two main divisions—one largely or entirely confined to the lymph vascular tissues and the other largely or entirely confined to the brain substance. In each of these two divisions varying numbers of spirochætæ and, even more so, varying sensitization of the tissues will occasion lesions of varying clinical importance. In the vascular tissues these will range from a slight meningitis to a gummatous process, while in the brain from a slight meningoencephalitis to tertiary encephalitis (dementia paralytica). It is admitted that these views are to some extent hypothetical, and are not founded upon a large pathological anatomical experience. This result is, however, due to the fact that the cases now recognized as encephalitis (Wassermann reaction and discovery of the spirochætæ) were formerly not recognized as syphilitic. The "cerebral syphilis" of the literature is practically confined to the gummatous processes. Further, since the patients are susceptible to treatment, a post-mortem examination is a rare occurrence. It is, nevertheless, certain from the rich clinical material and wide experience of Head and Fearnsides that the various syphilitic states the authors have referred to are common.

5. **Radium in the Treatment of Thyroid Hypersecretion.**—D. Turner believes that the favorable effects of the *x*-rays in thyroid hypersecretion can also be equalled by the action of radium. But in addition radium has two distinct clinical advantages over the *x*-rays: (1) a perfectly definite dose of it can be given and repeated as often as may be desired; and (2) the radium can be applied without noise or excitement while the patient is in bed. This is an important advantage in the treatment of this disease.

4. The Autoplastic Ovarian Graft and Its Clinical Value. B. Whitehouse.
5. Notes of a Supposed Case of Pellagra. R. Reid and W. Calwell.

1. **The Operative Treatment of Inoperable Cancer.**—C. Rowntree states that the operation for which he pleads is one deliberately undertaken with the sole object of removing the growth itself or as much of it as possible, in the hope of relieving much of the patient's discomfort, but with no expectation at all of permanently curing the disease. He believes that surgeons are not active enough in the treatment of inoperable cancer. The author is convinced that such operations have a far wider application than is generally accorded to them. It is true that operation occasionally seems to cause widespread diffusion of cancer, possibly from mechanical interference with the tissues, just as generalized infection is sometimes met with after operations for surgical tuberculosis. But there is no clear evidence that this rapid diffusion of growth is more frequent after operation in so-called inoperable cases than it is after operation in the early cases, and the

author therefore believes that it is not a matter of importance. It is also said that local recurrence takes place quickly after these partial operations, and that the last state of the patient is worse than if nothing had been done at all. Local recurrence takes place in a certain proportion of cases after any kind of operation; but even in these cases, when recurrence takes place comparatively early, the author does not believe that the condition of the patient is as bad as it would have been by that time, supposing no operation had taken place at all; and no one can deny that in many cases local recurrence never takes place at all—the patient dying a merciful death from visceral deposits after several or even many months of comparative comfort. There is a great deal of evidence in favor of the performance of limited operations for the alleviation of incurable cases of cancer.

2. **The Reaction of the Blood Serum in Cancer.**—W. D. Sturrock refers to the work of Moore and Wilson, who found that the free HCl is as definitely reduced in cancer of other parts of the body as in cancer of the stomach, and therefore concluded that the well-known reduction in this latter condition could not be due to local causes, but might, in common with the reduction in other cases, be due to "a change in the concentration in hydrogen ions in the plasma and lymph. It is at once evident that if a definite increase in the alkalinity of the serum can be detected in persons with cancer a valuable aid to diagnosis is secured, and the author's present study represents an attempt to determine whether the reaction will lend itself to clinical work. The author employed Moore and Wilson's method of determining the reaction of the whole serum to dimethyl as a measure of the degree of alkalinity. He found that the average alkalinity of the blood in cancer patients is appreciably higher than that of non-malignant patients.

4. **The Autoplastic Ovarian Graft.**—B. Whitehouse notes that one of the most important uses for this operation is as a conservative measure when it is necessary in a young woman to remove both uterine appendages for old-standing inflammatory disease without having to sacrifice the uterus. Another indication which he puts forward as a suggestion is the possibility of transplanting fragments of ovarian tissue in cases of severe dysmenorrhœa. Instances of most intense menstrual pain undoubtedly occur where the source of discomfort lies, not in the uterus, but in the ovaries. Curetting and drugs rarely cure such patients, and if an examination is conducted during the height of the attack the ovaries can frequently be palpated as extremely tender bodies occupying the posterior quadrants of the pelvis. In more than one case oöphorectomy has been and is still practised for this condition, and the author knows of instances where panhysterectomy has been performed. A cure is undoubtedly effected thus, but, the author asks, may not it be possible to bring about the same result without unsexing the patient, by substituting ovarian grafting? In conclusion the author summarized those points which he regards as essential to the success of a grafting operation: (1) Absolute asepsis and the avoidance of strong antiseptics which would destroy the vitality of the tissues. The apparent contradiction to this maxim in the case of chronic pyosalpinx and salpingo-oöphoritis is met by the fact that the pus in such cases is usually sterile, and the tissues may be treated as surgically "clean." (2) The employment of minute or "seedling" grafts. (3) The presence of a good vascular supply in the tissue used as the bed for the graft. Muscle is entirely satisfactory for the purpose. (4) The ovarian tissue should be left in contact with the body fluids within the peritoneal cavity until it is required for the purposes of the grafts. In the case recorded in this paper the ovary was placed in Douglas's pouch until the time arrived for closure of the abdominal wound.

Berliner klinische Wochenschrift.

September 22, 1913.

Sporotrichotic Osteoperiostitis of the Upper Jaw.—D'Agata mentions the great interest awakened by the ever-increasing number of manifestations and appends an instructive case of bone lesion of this origin. The patient was a youngish woman without children. Stock sound. At the age of 17 she was in Brazil and developed severe anemia, recovering after two years with the intensive and persistent use of arsenic. Married at 24, she never became pregnant, although her husband was strong and healthy. Two years later developed an osteoperiostitis on the shin bone, thought to have been tuberculosus, and treated as such with negative results. The purulent surface which had been exposed and drained was now regarded tentatively as syphilitic, but again failed to respond to treatment. The exposed surface finally healed spontaneously, just as a fresh lesion appeared over the cheek. This increased in size until it involved the upper gum and attacked the tooth sockets. A diagnosis was made of osteoperiostitis of the upper jaw. The condition, having reached a self-limitation, remained unchanged for ten months. Prolonged study finally excluded tuberculosis, syphilis and actinomycosis. By exclusion, aided by cultural efforts, a diagnosis of sporotrichosis was made. The peculiarity of this case appeared to be its début in the bony structures: for as a rule it attacks the latter as a result of disease of the soft parts, or the hard and soft parts are involved jointly. The rarity of the exclusive bone localization is shown by the fact that the case reported is the first known to have occurred in Italy.

Abbot's New Procedure for Scoliosis.—Vulpius states that this method is far too new to permit of a judgment of its ultimate value. After describing the method and the strictures upon it by German orthopedists, the author states that he has not yet seen a complete cure, but *x*-ray photographs which seem to show that cures undoubtedly occur. In regard to the disadvantages, one is atrophy of the bones. If scoliosis is due to bone insufficiency then this atrophy cannot be a desideratum. To offset this tendency we must do all possible to guard against weakening of the bones or general forces. Another drawback is increase of the accessory curvatures. Naturally attempts have been made to prevent this. No doubt the Abbot plan should be incorporated into our other resources. One great indication has not in the least been filled by Abbot—diminution of pains, time, and money. With the erection of small orthopedic sanatoria, this may in time become a vital element in the management.

Münchener medizinische Wochenschrift.

September 23, 1913.

Experimental Atherosclerosis and Cholesterinemia.—Wacker and Hueck conclude their study of this subject as follows: As a result of persistently increasing the cholesterin in the blood of rabbits the authors succeeded in causing a disease of the aorta which in essential points agrees with human atherosclerosis of the aorta. This brings to the fore the possibility of an atherosclerosis due to hypercholesterinemia—the more so as the latter condition is favored by other clinical and experimental data—increased muscle work, dyspnea, narcotics, adrenalin, etc.

Investigations into the Blood Serum of Gouty Subjects.—Ehrmann and Wolff have arrived at the following results: In diet free from purins the serum of normal man may still show uric acid in quantities large enough for measurement, while if the subject be typically gouty the uric acid in the serum may not equal the normal values. Hence in a typical gout so-called a little uric acid in the blood has no diagnostic significance. A recently highly recommended patented remedy for gout has no power to

lessen the uric acid in the blood, while in the ordinary total mass of blood purins are from four to ten times more abundant than is uric acid, the serum alone shows more uric acid than purins. The concentration of H ions in the blood of the gouty is often considerably greater than that of the normal blood, and also of diabetics with coma and precoma. Hence the alkalinity of the blood may be decreased in gout. The blood serum of the gouty occasionally has a slight lipoid look.

Thorium-X in Internal Disease.—Meseth writes at great length on this subject, his article being virtually a monograph, in addition to his own large experience. Thus he has treated three cases of myelogeneous leucemia. One of the three patients showed notable improvement, while the others were practically uninfluenced, despite initial improvement. Lymphatic leucemia was much more resistant to the remedy. Secondary anemias showed more improvement after removal of the cause than is ordinarily expected. Pernicious anemia, made worse at first by treatment, showed afterward some short-lived improvement. Thorium-X is evidently too severe a remedy to combat this blood affection because of its general weakening effects. In one case of obesity no loss of weight resulted. In lymphosarcoma with gland metastases thorium exerted a definite influence, which, however, was not marked. Quite a degree of improvement occurred in a case of multiple lymphoma. In sharp contrast from most of the preceding results is to be noted astonishing improvement in two cases of focal affection of the spinal cord of uncertain origin. In a large number of cases of chronic rheumatic arthritis treated some results were strikingly good, and under small dosage, which makes a desirable combination. In these affections and in the secondary anemias thorium X can be depended on to a large extent for good results gained without risk.

Deutsche medizinische Wochenschrift.

September 11 *and* 18, 1913.

Recovery in a Case of Tetanus Neonatorum.—Wolff states that the mortality of this affection varies from 70 to 95 per cent. We know that the latter is identical with ordinary tetanus, because if matter from the navel of children who are victims of this disease is injected into experiment animals tetanus results. When we consider that the dirty treatment of the navel of the newly born at the hands of mothers and midwives has caused most of the recorded cases in the past, the simple cleanliness of the present day must have greatly lowered the incidence of tetanus. Aside from prophylaxis not much progress has been made in life saving, even under the most modern plans of treatment. The author's case is as follows: A boy aged eleven days was brought to the clinic by his mother who stated that for the past two days he had suffered the most violent convulsions. The cord had sloughed at the eighth day, the stump having been dressed by the midwife. Pus soon appeared at the navel, and trismus had developed two days later. This very brief interval caused some doubts as to diagnosis despite the absoluteness of the clinical picture. In the interest of the child no attempt was made to excise a portion of the navel for miscroscopic study. According to precedent the chance of finding bacilli would have been small. Hence serum was at once injected, 300 units distributed in various places. As is well known, it is difficult to supply the calorie requirements of a young infant with tetanus. The patient was narcotized with bromides and chloral until it could be fed with milk by the stomach sound; these remedies also controlling the convulsions. At times the chloral was given in the milk. This treatment was kept up until the child was able to nurse. The milk was obtained directly from the mother's breast. The disease ran a severe course, convulsions being of the most violent type and fever correspondingly high. The calorie plan of feeding was maintained and the author does not know whether to give the most credit to the serum, chloral, or sound feeding.

Functional Testing of the Liver.—Strauss refers to the literature of the past 12 years concerning the efficacy of the levulose test for estimating the functional activity of the liver and states that his own experience is in full agreement with that of others. He also gives equal credit to the galactose test recently introduced by R. Bauer Positive results are obtained more infrequently in obstructive jaundice and more frequently in neurogenic functionl disturbance of the liver. Many minor problems require solution. The author says that the two tests—levulose and galactose—should for the most part be used on the same subject.

Regeneration of the Thymus Gland in Mammalia.—Fulci states that regeneration of this organ in mammals occurs alike in the young and adults. This fact, with the persistence of normal thymus structure in aged animals, shows that the organ is as necessary to extrauterine as it is to intrauterine existence. The author adds that the lymphocytoid thymus cells really give birth to epithelial structures which possess regenerative powers. The medullary cells and Hassal's corpuscles are also gradually developed from the lymphocytoid cells. We may conclude that the thymus is essentially an epitheloid structure supported by a vascular substratum.

Arteriosclerosis and Allied Subjects.—The three leading articles of this number are devoted to clinical and experimental arteriosclerosis and paroxysmal tachycardia. Hirsch opens with the pathogenesis and physics of arteriosclerosis. He brings the latter in direct connection with elasticity of the vessels. There is, however, much confusion as to what elasticity really is. It may be complete or incomplete. Normal arteries are completely elastic. The operation of the deforming forces tends to increase the deformity; and when these are withdrawn the *restutio ad integrum* does not at once take place. A certain amount of elasticity results as an after-effect, controlled perhaps in part by innervation. In arteries which are notably exhausted, or influenced by poisons, this secondary elasticity may constitute a grave menace. In early arteriosclerosis it is easy to note a lack of elasticity; but later on this is not an even expression of the disease, as numerous other factors may have developed—sclerosis, degeneration, calcipeation. Loeb considered experimental arterial alterations on rabbits and dogs in which lactic acid was the agent employed. His work is still in progress, so that no conclusions are drawn, but the author claims that for the first time he has succeeded in producing arteriosclerosis in an animal other than man. He disputes the assertion of Boveri that arteriosclerosis may be caused in apes by injecting adrenalin. The author's rabbits did not develop the disease. In two dogs, however, in which the intima was attacked, a condition was produced very much like human arteriosclerosis. Dogs seldom develop the disease spontaneously, and even in very old dogs the findings in this respect are conflicting. Kaufmann and Popper, who consider the pathogenesis and treatment of paroxysmal tachycardia with alternations of arrhythmia and allorhythmia, were able to demonstrate this anomaly was due to Tawara's nodes by the use of the cardiosphygmograph. When arrythmia coexisted it is due to a change in the point at which the cardiac contraction begins, and also to a certain degree of sinoauricular block. Large doses of physostigma plus strophanthus caused the cessation of the tachycardia, while the arrhythmia assumed another type (*a perpetua*). The latter type in turn is abolished by atrophin. These indications and prescriptions for their relief are worked out wholly by sphygmo- and electrocardiagrams.

Insurance Medicine.

Insurance Against Occupation Disease In Germany and Foreign Countries.—Curschmann states that compensation for accidents due to occupation is in many countries older than legal insurance against disease. In the former it is often difficult to connect the occupation with the disease. Hence there is the closest possible relationship between the workman, his occupation and the disease. A single act of injury is insufficient—there must be a gradual deterioration of health. Hence a disease of occupation must be one extending over a long period, based on the particular kind of labor in which various factors produce a disease which could not arise in the absence of any one of them. The disease should be serious in type, and the patient should have been in good health before developing the malady. All factors must act not only conjointly but synchronously. The list of occupation diseases recognized in Germany, at present twenty-four, is best represented by placing the essential factor first, and the workers exposed to it later, as *malignant pustule,* the essential factor in occupation diseases in which the subjects are workers in wool, hair, brushes, hides and pelts; *lead poisoning,* which occurs in workers in any factory in which lead or substances containing lead are used; *hydrargyrism,* in which mercury is correspondingly employed; *phosphorous poisoning,* which appears in any kind of manufacture in which that subject is used; *arsenical poisoning,* under analogous circumstances. The majority of these poisons cause simply the symptoms of such poisons. We then have ankylostomiasis, occurring in mining, with four other (all mechanical) affections peculiar to miners. To these five must be added miner's nystagmus. Glassblower's cataract, caisson disease, telegrapher's cramp, are three isolated examples of occupation diseases. Chronic ulcers naturally attack those who use chromine; the benzoles, carbon disulphide, nitrous gas and other poisonous fumes only cause occupation disease in those who actually work with them; workers in pitch, tars, etc., are liable to dermatitis and cancer. Finally glanders is placed as an occupation disease. These facts seem at first sight trite, but they simply indicate that this series of occupation disease has passed muster over and over under experts. Numerous other affections are, so to speak, on the waiting list of approval. The subsidiary factors, in virtue of which one contracts what another escapes, are not much mentioned. At present a committee is endeavoring to fix the status of cowpox, Dupuytren's contracture, and clinical blepharo-spasm. Numerous writers have their favorite occupation diseases, which are not yet incorporated in the list, such as chronic manganism of manganese workers, and the osteitis of workers in mother of pearl.—*Zeitschrift für die gesamte Versicherungs-Wissenschaft,* March 1, 1913.

Scars Upon the Body of a Candidate for Life Insurance.—Dr. Grohmann holds that any scar upon the body of an applicant suggests a something abnormal: for example, that a man born sound has experienced violence of some sort or has produced himself an artifact for one purpose or another. The author better conveys his meaning by cases. Thus an applicant aged thirty-five was examined for insurance. He was sound at birth, and had only an enlarged lymphnode which seemed to be connected with some bad teeth. Recently it had become very painful and the applicant was rejected. Later on operation became necessary, but no pus pocket was present at the time. As the operation wound healed there remained behind a dental fistula. A radical operation led to a complete cure of the latter and the applicant was accepted. In such a case the scar, indicating a radical cure of the only known defect, is evidence of a good rather than a questionable condition. Another applicant had a fear of rejection because of an operation on the ear (mastoidectomy) which had been followed by a disfiguring scar. There was a suspicion of tuberculosis of the middle ear. The author had not the courage to recommend the man despite his apparent robust health. Nevertheless he was living and well many years later. Two facts played a great part in the author's caution. First, the adherence and retraction of the scar following mastoidectomy, and second, a history of former ear discharge. The whole history suggested otitis media and empyema of the antrum.—*Blätter für Vertrauensärzte der Lebensversicherung,* May-June, 1913.

Association of Life Insurance Medical Directors of America.—The twenty-fourth annual meeting of this Association will be held in Philadelphia on Wednesday and Thursday, October 29 and 30, in the Board Room of the Penn Mutual Insurance Company, 925 Chestnut street. Besides the general business which will be brought before the association, papers will be read by the president, Dr. Harry Toulmin, medical director of the Penn Mutual Life Insurance Company; by Dr. E. W. Dwight, medical director of the New England Mutual Life Insurance Company, on "The Value of Small Classes"; by Dr. R. L. Lounsberry, medical director of the Security Mutual Life Insurance Company, on "The Mortality Experience in the Total Abstinence Class"; by Dr. J. A. Patton, associate medical director of the Prudential Insurance Company, on "The Surgical Kidney with Reference to Life Insurance"; by Dr. W. Muhlberg, assistant medical director of the Union Central Life Insurance Company, on "A Few Practical Observations: the Result of Eight Thousand Examinations of Urine"; and by Dr. G. A. Van Wagenen, medical director of the Mutual Life Benefit Insurance Company, giving the Report of the Committee on the Blood-Pressure Test. The annual dinner of the association will be held on Wednesday, October 29, at 6:30 P.M., at the Rittenhouse Club, Philadelphia. The secretary of the society is Dr. Faneuil S. Weisse, 34 Nassau street, New York.

Nervous States in Relation to Insurance.—Lankford suggests that among the questions asked on the medical application blank a few be inserted that would bring out more fully the state of the nervous system of the applicant. As a nation, we are under an extreme nervous strain all the time—the question of a man's occupation and the length of hours he puts in at his work, his relations in his family life, in his personal matters as well as his work, all have an influence on the reflexes. There is no doubt but this nerve strain affects the internal secretions, such as those of the thyroid, and the adrenal system, and leads to autointoxications which are extremely bad in life insurance.—American Life Convention, Medical Section.

Book Reviews.

Drei Vorträge Ueber Tuberkulose. Von Johannes Orth, Professor der Universität, Berlin. Price, 2 marks. Berlin: August Hirschwald, 1913.

The name of this well-known authority on pathology, who now occupies the chair which was graced for many years by the immortal Virchow, is a guarantee of the scientific value of these three lectures. Two of them treat of the relation of tuberculosis in cattle to tuberculosis in man. The other is a splendid review of our present knowledge of tuberculous reinfection and its bearing on phthisiogenesis in the adult. For want of space we can only refer here to two of the most striking statements expressed in Professor Orth's invaluable contribution: First, that even granted that every tubercle bacillus of the human type could be suddenly annihilated, tuberculosis in the human race would still continue as long as the bovine type can be transmitted to human beings. In the second lecture, condemning the attitude of Herr Kirchner, the director of the medical division under the Secretary of the Interior, who claims that tuberculosis cannot possibly be caused by the ingestion of milk from tuberculous cows, but only by contact with tuberculous human beings, Professor Orth rejoices in the opportunity to join in the fight with the *Kaiserliche Gesundheitsamt* against the bovine as well as the human bacillus.

Les Ictères Toxiques et Leur Traitement. Par Noël Fiessinger. Ancien interne lauréat des hopitaux. Chef de Clinique Therapeutique à la Faculté de médecine de Paris. Price, 2 francs. Paris: A. Maloine, Editeur, 1913.

This is a pleasantly written little pamphlet on a subject which is treated with rather scant courtesy in most of the textbooks. Jaundice of infectious origin looms so large in the clinicians' horizon that little consideration is usually given to the form due to non-bacterial causes. Fiessinger takes up seriatim the agents capable of producing the icteric syndrome, such as phosphorus, arsenic, lead, chloroform, salvarsan, etc., and discusses the resulting clinical picture, as well as the types of icterus associated with diabetes uremia, disorders of the alimentary canal, blood diseases, etc.

Berechnete Ärztliche Kostverordnung. Nebst vollständigem Kochbuch für Zuckerkranke. Von. Dr. med. Hermann Schall. Price, 5.50 marks. Würzburg: Curt Kabitzsch, 1913.

There are already numerous cook books for diabetics available, but none of them prepared with the elaborateness of the present one. In addition to recipes for 550 dishes, each with its components tabulated in respect to fat, proteid, carbohydrates, and caloric value, there are 575 complete daily menus of five meals each, also completely tabulated, and graded according to the quantity of carbohydrate. The volume is of the sort which are made only in Germany, and though a stomach to relish some of the preparations described would probably have to be of the same origin the book contains an immense amount of useful culinary information and may be warmly recommended to those who have many diabetics to treat.

Laboratory Methods. With Special Reference to the Needs of the General Practitioner. By B. G. R. Williams, M.D., Member of Illinois State Medical Society, American Medical Association, etc. Assisted by E. G. C. Williams, M.D., formerly Pathologist of Northern Michigan Hospital for the Insane, Traverse City, Mich. With an introduction by Victor C. Vaughn, M.D., LL.D., Professor of Hygiene and Physiological Chemistry and Dean of the Department of Medicine and Surgery, University of Michigan, Ann Arbor, Mich. Second Edition. Illustrated with forty-three engravings. Price, $2.50. St. Louis: C. V. Mosby Co., 1913.

The object of this volume is so praiseworthy that its occasional minor deficiencies may well be overlooked. Few consummations are so devoutly to be wished as that the general practitioner, and especially the one who is compelled to do his work in more or less remote regions, should be induced to take a greater interest in the laboratory methods and to realize how absolutely essential many of them are to correct diagnosis. Not a few of them can be carried out with the simplest equipment in the way of apparatus and chemicals, and with a comparatively small expenditure of time, and it has been the aim of the authors to assist the inexperienced worker in selecting the procedure best adapted to his needs and capacities. For the most part their teaching conforms with the accepted doctrines and much ingenuity is shown in the suggestions as to how appliances may be improvised out of materials at hand. The field covered is a wide one, for not only are the usual subjects of laboratory diagnosis discussed but there are also sections on the technique of section cutting, performing antopsies, water analysis, the identification of poisons, etc. Of course, where the attempt is made to cover so much ground the discussion of many topics must necessarily be much abbreviated, and in the case of the chapter on the blood, for example, this is particularly noticeable. Probably few diagnoses are more often wrongly made through lack of laboratory investigation than that of malaria, so that it hardly seems fair to the beginner with budding yearnings for scientific accuracy to put him off with the terse statement concerning the plasmodium that "it is not the purpose of this book to enter into a discussion of the morphology of this microorganism.' The volume is characterized by much originality in the method of presentation and contains a great deal that will be of interest to all medical readers.

An Elementary Study of the Brain. Based on the Dissection of the Brain of the Sheep. By Eben W. Fiske, A.M., M.D. Illustrated with photographs and diagrams by the author. Price, $1.25 net. New York. The Macmillan Company, 1913.

This little book is intended by its author to serve as a laboratory manual for the student, as well as a biological study of the development of the brain in the race and in the human individual. Interest in the subject is stimulated by frequent supplementary references to function of parts, and when practicable to psychological aspects. In regard to nomenclature, the author has employed names both from the older terminology and from the Basel association. He also uses terms borrowed from the human rather than the mammalian nomenclature in most instances. The bibliography at the end of the book (only twelve references) seems rather scanty. We note, for example, no allusion to the great work of Wilder of Cornell or Obersteiner of Vienna. There are 19 figures and 14 photographs in the book. The sheep's brain was used for the dissections "because of its general availability, relative simplicity, and practical identity to that of man." The chapter headings include Phylogeny, Ontogeny, Removal of the Brain, and the Anatomical Surfaces and Sections. The subject is presented as clearly, perhaps, as can be in this way, and the author is deserving of much credit for his own original work.

Diseases of the Skin. A Handbook for Students and Practitioners. By Dr. David Walsh, M.D., Edinburgh, Senior Physician, Western Skin Hospital, London; President of the New London Dermatological Society. Price, $2.50 net. New York: William Wood & Company, 1913.

This is a very useful and practical handbook on diseases of the skin. Special allusion has been made to the relation of skin diseases to the human body generally and also to the relation of various skin diseases to the vascular system. The latter has been very much neglected by dermatologists. It is regrettable that from the present state of their knowledge it has been impossible to draw up any satisfactory scheme of classification, but the following seems to the author to be of value and one that he employs: Disorders of circulation; disorders of nerve origin; common inflammatory dermatoses; disorders of the sebaceous glands; disorders of the sudoriferous glands; disorders of the hair and nails; disorders of pigmentation; disorders of vascular origin; hypertrophic and atrophic dermatoses; new growths (neoplasms); parasitic dermatoses; certain general diseases affecting the skin. In the appendix is a description of the Wassermann test. This book will be useful as a guide to students and practitioners as well.

Causes of Death Among Woman and Child Cotton-Mill Operatives. Prepared under the direction of Chas. P. Neill, Commissioner of Labor. By Arthur R. Perry, M.D. Washington: Government Printing Office, 1912.

This is Vol. XIV of the report on condition of woman and child wage-earners in the United States. The study was undertaken to secure the most accurate information obtainable respecting the death hazard to males and females incident to work in cotton mills, as compared with the corresponding hazard among individuals of like age who are not cotton-mill operatives. The investigation disclosed the fact that in the country's largest cotton manufacturing city not even one-half of the females who had died two years or less after quitting cotton-mill work were recorded upon the official death certificates as having been cotton operatives.

Summaries of Laws Relating to the Commitment and Care of the Insane in the United States. Prepared by John Koren for the National Committee for Mental Hygiene. Price, $1.00. New York: Published by the National Committee for Mental Hygiene, 1912.

The insanity laws of the various States vary considerably from one another. Some of them seem to be very inadequate. These laws were first brought together in condensed form over twenty years ago by Clouston and published in the back of his book on Mental Diseases. The public care given to the insane in the various States is reflected in their laws in almost every case. A book of this kind, widely disseminated, is calculated to awaken public interest in the insane and in any measures undertaken for their general welfare. Hardships still exist in some States for these unfortunates, although all the up-to-date methods of treatment for persons suffering from other diseases (*e.g.* tuberculosis, diphtheria), may have been adopted by the various boards of health in the same States and put into operation. The old idea that the insane required custody only has given way to the modern conception of hospital and individual treatment. The new ideals are not reflected in the legislation of all of the States as set forth in their laws as they are stated in this useful book. The matter contained in the summaries has been gathered in each State under the following headings: Administration and Supervision; Provisions for the Care of the Insane; Commitment; Conveying Patients to the Hospital; Transfer of Patients; Parole and Discharge of Patients; Cost of Maintenance; Criminal Insane.

The Modern Treatment of Nervous and Mental Diseases. By American and British authors. Edited by William A. White, M.D., Superintendent of the Government Hospital for the Insane, Washington, D. C.; Professor of Nervous and Mental Diseases in the Georgetown University; Professor of Nervous and Mental Diseases in the George Washington University; Lecturer on Mental Diseases in the U. S. Army and U. S. Navy Medical School, Washington, D. C.; and Smith Ely Jelliffe, A.M., M.D., Ph.D., Adjunct Professor of Diseases of the Mind and Nervous System in the Post-Graduate Medical School and Hospital; Visiting Neurologist to the City Hospital; Consulting Neurologist to the Manhattan State Hospital, New York. Vol. II. Price $6.00. Philadelphia and New York: Lea & Febiger, 1913.

The practical value of this volume is amply indicated by the wide scope of the articles composing it. These are of monographic character and embody the most recent thought and practice in neurology. These articles are as follows: The Treatment of the Neuralgias and Neuritides, by S. L. Schwab; The Treatment of Injuries to the Peripheral Nerves, by J. Sherren; The Treatment in the Muscular Atrophies and Dystrophies, by Isador Abrahamson; The Treatment of Headaches, by S. E. Jelliffe; The Treatment of Spasmodic Disorders, by H. H. Hoppe; The Treatment of the Epilepsies, by J. F. Munson; The Treatment of the Meningitides, by W. J. M. A. Maloney; The Treatment of the Syphilitic Diseases of the Nervous System, by S. E. Jelliffe; The Use of Salvarsan and Neosalvarsan in Diseases of the Nervous System, by H. J. Nichols; The Treatment of Cerebral Hemorrhage, Embolism, and Thrombosis, by F. Tilney; The Treatment of Disorders of Expression (Aphasia, Apraxia, etc.), by S. H. Kinnier Wilson; The Treatment of Stuttering, by E. W. Scripture; the Treatment of Diseases of the Cranial Nerves and Organic Lesions of the Spinal Cord, by C. K. Russell; Dseases of the Optic Thalamus, Midbrain, and Cerebellum and their Treatment, by Gordon Holmes; Paralysis Agitans and Multiple Sclerosis and Their Treatment, by C. D. Camp; The Treatment of the Toxemias of Dangerous Trades and of Drugs, by L. Casamajor; and Surgery of the Brain and Spinal Cord, by A. E. Halstead and R. T. Vaughan.

Krankheit und soziale Lage. Herausgegeben von Professor Dr. M. Mosse, Berlin. und Dr. Med. G. Tugendreich, Berlin. 4. Lieferung. Munich: J. F. Lehmanns Verlag, 1913.

This is the fourth and concluding number of this important work on disease and social condition. It contains the following articles: The governmental control of the social causes of disease, by F. Zahn and J. Kleindinst; the principles of public and private relief measures, by A. Gottstein; the influence of social laws upon the prevention, recognition and evolution of diseases, by A. Fischer; and social measures for the betterment of the future race, by W. Schallmayer. Such subjects as the prevention of child labor, factory laws, the protection of maternity and infancy, the regulation of the liquor traffic, workmen's insurance, and eugenics, are all discussed with the thoroughness and insight characteristic of German writers. In completing their work on the social aspect of disease the editors have admirably acquitted their task in making a unique and substantial contribution to medical literature.

Sterility in the Male and Female and Its Treatment. By Max Huhner, M.D., New York; Chief, Genitourinary Department, Harlem Hospital Dispensary; Attending Genitourinary Surgeon, Bellevue Hospital Out-Patient Department; and Assistant Gynecologist, Mount Sinai Hospital Dispensary, Member American Urological Association, American Medical Association; Fellow of the New York Academy of Medicine, etc. Price $2.00. New York: Rebman Company, 1913.

This book has the merit of being chiefly the report of the author's original observations on the causation and treatment of sterility. He has approached the subject with a comprehensive knowledge of what others have written about it, but he has employed new methods in its investigation and as a result has been able to contribute many important data regarding sterility in the male and in the female. As to the responsibility of the male in a sterile marriage the author lays down the rule that if the spermatozoa reach the cervical os in a normal condition the male is absolved from all responsibilities in the causation of sterility. The author states that this is the only absolute test that the male is normal. Therefore, instead of examining a condom specimen for spermatozoa it is more important to obtain a particle of mucus from the cervical os shortly after coitus, and to examine this specimen for spermatozoa. If live spermatozoa are found the husband is absolved from responsibility in the production of sterility. Other important facts brought out by the author's painstaking investigations are the following: Vaginal douches after coitus to prevent conception are not certain in accomplishing this result. If a long conical cervix is present, its amputation may enable the semen to be more easily ejaculated upon its surface. *Effluvium seminis* is not a cause of sterility, for it is only the semen that is on the cervix that causes impregnation. Alkaline douches taken before coitus are useful in certain cases of sterility and help to preserve the vitality of the spermatozoa. The importance of the author's study may be realized when it is considered that 10 per cent. of all marriages are sterile. The author has made a series of important investigations as to the influence of chemicals and secretions upon spermatozoa, and has developed a technique for performing aspiration of the testicles as a means of determining the exact condition of spermatozoa nearest to their source. He discusses the practical hopelessness of azoospermia, although the condition is sometimes improved by the treatment of the prostatic urethra. He finally presents in detail his distinctly original method of procedure in the treatment of sterility in the male and female. A full report of cases and an adequate bibliography conclude the volume. Although his literary style, as may be judged by the use of such expressions as "it cannot be emphasized too emphatically," can be greatly improved upon, there can be no doubt that the author has made an important and substantial contribution to medical literature.

The Examination of Waters and Water Supplies. By John C. Thresh, D.Sc. (Lond.); M.D. (Vic.); D.P.H. (Camb.), Medical Officer of Health, Essex County Council, etc. Second Edition. Price $5 net. Philadelphia: P. Blakiston's Son & Co., 1913.

It is gratifying that a second edition of this work has so soon been found necessary. The position of the author is such that his experience in this kind of work has been very extensive and the results as expressed in this book show that he has been able to correlate this experience and draw from it conclusions which should be of great benefit to others doing similar work. The technical portion of the book is exceptionally complete and satisfactory, but those chapters on the interpretation of results thus obtained are the ones likely to prove most valuable. It is especially good to see that the author insists upon the importance of the examination of the source of a water supply as well as the chemical and bacteriological examination of the water itself. The former is only too apt to be neglected and it is not sufficiently realized that such an examination will give information as to a liability of a water to contamination while examination of a single sample determines the character only of that sample and furnishes no guarantee for the future. The book can be highly recommended.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-sixth Annual Meeting, Held at Providence, R. I., September 16, 17, and 18, 1913.

The President, Dr. Miles F. Porter, Fort Wayne, Indiana, in the Chair.

The Treatment of Puerperal Streptococcemia with Intravenous Injections of Magnesium Sulphate.—Dr. James A. Harrar of New York City stated that the use of magnesium sulphate intravenously for the treatment of puerperal infection was first proposed by Dr. R. R. Huggins in 1910. Impressed with the results obtained by Dr. Huggins and interested in any means of combating the ravages of puerperal infection, Dr. R. W. Lobenstine, upon his return from the meeting at which Dr. Huggins read his paper, tested the method at the New York Lying-In Hospital with more or less success. He effected a cure in three cases of streptococcic toxemia of the fulminating type that was so frequently fatal, and in one case of streptococcic bacteriemia. His fifth and last case, one of streptococcic toxemia, but with negative blood cultures, resulted fatally, and rather discouraged him in the efficacy of the treatment. In continuation of this work Dr. Harrar said he had employed the salt intravenously in 9 additional cases of the severer type of puerperal infection, the bacteria having been demonstrated in the blood of five. The total series of 14 cases, with complete recovery in 12, had prompted him to present fever charts as clinical evidence of the value of this adjunct to our present means of dealing with puerperal infection, especially of streptococcic origin. A 2 per cent. solution of chemically pure magnesium sulphate was prepared with freshly distilled water. This was filtered and sterilized in half liter flasks in an autoclave. This solution will not hemolyze human red blood cells, and he had found by experience that prepared in this way it would not cause any temperature reaction in the patient. Formerly a 1 per cent. solution of magnesium sulphate in physiological salt solution was employed, and a chill or sharp temperature rise frequently followed the injection. The author drew the following conclusions: 1. In the quantities and dilutions described, magnesium sulphate was absolutely harmless when administered intravenously to women suffering with puerperal infection. 2. Magnesium sulphate was of more value early in the course of the infection than after secondary localization had occurred. In the chronic cases of secondary thrombophlebitis or pyemia it did not appear to be of benefit. Its action was chiefly upon the organisms circulating in the blood. 3. It shortened the course of the bacterial toxemias in which the bacteria could not be demonstrated in the blood by culture, and anticipated the establishment of a bacteriemia, and finally it had reduced the mortality in puerperal bacteriemia, especially in streptococcemia, the most fatal form of puerperal infection, from 93 per cent. to 20 per cent.

Dr. Ross McPherson of New York said he had had very little experience with the actual treatment that Dr. Harrar had described except in watching his results. Only one case had come under his observation, which was not a true bacteriemia, and this case did very well. The results described by Dr. Harrar were nothing short of marvelous as one saw these patients improved under magnesium sulphate.

Dr. Asa B. Davis of New York said he had watched with interest, surprise and gratification the work which had been done by Dr. Harrar in the cases that had come in his service, and he could confirm what Dr. Harrar had said.

Dr. Herman E. Hayd of Buffalo thought the results obtained by Dr. Harrar with magnesium sulphate in puerperal infection ought to stimulate all members of this association to try this treatment and at some future meeting relate their experiences in regard to it.

Dr. Gordon K. Dickinson of Jersey City said we were all interested in other types of bacteriemia, and if Dr. Harrar could give us some points in the matter of pneumococcemia and the coccemias of other germs, it might instigate experimentation in different lines than those mentioned.

Dr. Budd Van Sweringen of Fort Wayne said that if it be true that the establishment of an abscess in the lung, as in this one case the doctor recited, was responsible for the cure brought about, it bore out the contention of a Frenchman who wrote upon the establishment of abscess in these conditions by the injection of turpentine into the tissues of the thigh or back or any available place. He imagined the good results reported by the author at that time were due to a biological process, perhaps the establishment of antibodies in this "fixation abscess," as he called it, and whatever the theory might be a number of cases of his own were treated in that way as well as others he had knowledge of and were followed by improvement. He had had no experience with the injection of magnesium sulphate, but he would like to know whether any of the Fellows had employed this fixation abscess method in streptococcic infections, and what results they had had with it.

Dr. Roland E. Skeel of Cleveland said that we reported our wonderful successes, but did not report our failures. These observations and investigations should be followed up until it was proven that sulphate of magnesium did what was claimed for it in puerperal infections.

Dr. Joseph H. Branham of Paltimore said that if all members of the association would carry out this method of treatment in cases of puerperal infection, in one year they would have absolute demonstration beyond a doubt of what there was in this treatment.

Dr. H. Wellington Yates of Detroit said it seemed to him the essayist attached very little importance to the toxicity of magnesium sulphate. In the report of cases he found that in each instance in which the magnesium sulphate was injected, there followed a distinct chill with rise in temperature. Therefore, magnesium sulphate should be used with care.

Dr. Edward J. Ill of Newark suggested that anyone who attempted to carry on these experiments with magnesium sulphate should not attempt to improve on the method adopted by Dr. Harrar, but wait until his paper was published, study it carefully, and then carry out the method as he had described it.

Dr. E. Gustav Zinke of Cincinnati said that this was a new method and had apparently been practiced with success, and it was our duty to take it up and determine what there was in it.

Dr. Harrar, in closing the discussion, stated that, as to the use of magnesium sulphate in other pathological conditions or infections, he had no experience with it except in one case of pneumococcic infection which occurred in the course of puerperal infection. In her case it was of no value. He did not feel prepared to make any final statement relative to the exact value of magnesium sulphate in puerperal infections, because he had not seen enough cases. However, sulphate of magnesium was certainly of value and well worthy of trial.

Lactation Atrophy of the Uterus.—Dr. Douglas H. Stewart of New York stated that with lactation atrophy the breasts either produced too much mammary extract, and the uterus wasted away as a fibroid sometimes would when powdered cow's udder was administered, or the secretion drained off in the milk, some hormone which should stimulate the circulation, nutrition and growth of the uterus after the normal or physiological atrophy of the fifth month of lactation, and the physiological process became pathological in time. In case No. 1 of his series he made the circulation right. After that lactation ceased, and growth and menstruation started at once.

Dr. Ross McPherson of New York said he had wondered after seeing the case reported by Dr. Stewart, whether the secretion which was present in her breast was not the secretion that was found in many cases of pelvic disturbance. As soon as the disturbance in the pelvis was relieved, the secretion disappeared. The condition was interesting and rather unusual. He had not before seen a case of lactation atrophy that presented such symptoms.

Dr. David Hadden of Oakland said in a case he operated on two years ago there was no lactation connected with the menstruation. The woman had a baby four years before the time he saw her, and had not menstruated. Her uterus was retroverted, and both ovaries were prolapsed. There was a deep laceration of the cervix and an ulcer. He corrected these conditions, and two months after operation she began to menstruate and had since menstruated every month, the flow being practically normal.

Dr. Hugo O. Pantzer of Indianapolis said that the paper called attention to a class of cases that were too little touched upon in medical literature. About 25 years ago he confined a woman who had all her previous life been in frail health. After being married for one year she conceived and had a child at full term. It was a forceps delivery. There were no complications incident to child bed. The child, in contrast with the mother, thrived wonderfully, and was nursed for two years. The family

were very anxious to have offspring, and the woman came to him at about the third year. He found a small atrophic uterus and complete amenorrhea of some years' standing. It was fair to associate amenorrhea and atrophy of the uterus with excessive lactation. General remedies and the use of an intrauterine stem for a period of three or four months brought back menstruation, and the patient conceived again.

A Contribution to the Serology of Pregnancy.—Dr. HENRY SCHWARZ of St. Louis said that it had been proved by the observations of many investigators that in diseased conditions of the various organs of the body, likewise in malignant disease and also during pregnancy the blood was contaminated by cell albumin from the affected organs, the malignant cells and the chorionic villi, and that the organism responded to the entrance of this blood foreign material by the mobilization of ferments which affected the intravascular digestion of these proteins. It had also been proved that such ferments were not present in the blood of normal individuals. The protoplasm differed in these various tissues. This difference could be demonstrated by biologic methods. These same methods proved that there was less difference between protoplasm from the same organs in different species than there was between the protoplasm of two different organs in the same individual. For example, there was less difference between the liver protoplasm of a dog and the liver protoplasm of a sheep than there was between the liver protoplasm of this dog and his kidney protoplasm. The protective ferments were specific. The serum of non-pregnant cancer cases would cause cleavage of cancer albumin, but not of placental albumin, and the serum from a non-cancerous pregnancy case would cause cleavage of placental albumin, but not of cancer albumin. In the department of obstetrics of the Washington University Medical School Abderhalden's biological tests were used for the differential diagnosis of pregnancy; also for the early diagnosis of malignant disease and the control of such cases after radical operation. The biological test had been applied in more than 100 cases, partly in experimentation, and in a dozen cases as an actual and much needed help in diagnosis. Petri's claim that reinjecting an individual with some of his own serum would cause the appearance of nonspecific ferments was tested by repeating the experiments. The result was absolutely negative. Petri's second claim, that adding active serum to inactivated pregnant serum would not restore the cleavage power, had already been disproved by Steising. Steising's experiment had been repeated four times, but always with positive results. In the service of the New York Lying-In Hospital and in the obstetrical service of the University of Pennsylvania and of Washington University, all toxemic and eclamptic cases were at present examined as to the degree of cleavage power of the serum. Where such power was impaired or absent the attempt was being made to correct the conditions by injecting normal pregnant serum. It was hoped that such cooperation would in due time furnish reliable information on this subject.

Abdominal Cesarean Section.—Dr. ASA B. DAVIS of New York presented the statistics with results for mother and child in the whole series of cases in which he had done this operation; likewise the indications for the operation. He described the technic of the operation by a small median incision which is made above the umbilicus.

Treatment of Placenta Prævia by Cesarean Section; When, if Ever, Is It Justifiable?—Dr. ROSS MCPHERSON of New York stated that since 1891, in the service of the New York Lying-In Hospital, there had occurred 470 cases of placenta prævia, and the operation of cesarean section had been performed for this condition 19 times by six different operators, all since 1905. The situation of the previa was central in 9 cases, marginal in 5 cases, and no statement as to situation was made in the history of 5 cases; no case was more than two fingers dilated; all had had severe hemorrhages before entrance into the hospital, and in all it was a matter of rapid delivery being considered advisable. The patients varied from Para I to Para XIV; the youngest was 18 and the oldest 38. As to the results, of the 19 cases operated upon, one mother died, a maternal mortality of 5.3 per cent., two children were still born, and 3 died before leaving the hospital, 2 on the first day, and one on the ninth, a fetal mortality of 5 or 26 per cent. He believed that the indication was clear, that when we encountered a primipara with a placenta prævia either marginal or central, or a multipara, with a central placenta prævia, in either case where the cervix was rigid or undilated, whether or not there was pelvic disproportion, provided the child was viable and the mother offered the ordinary safe operative risk, cesarean section held out a better chance of saving the lives of both mother and child with fewer complications than any other method of delivery, always provided that the operation was performed by a competent and experienced operator and amid suitable surroundings.

The Advantage of Cesarean Section Over Other Procedures in Borderline Cases.—Dr. JOHN WILSON POUTHER of Poughkeepsie reported 5 cases of cesarean section, and in all of them he used the high abdominal incision, opening the uterus *in situ* as often as it was exposed, carrying the uterine incision well over the fundus. With this incision the operation could be done through an abdominal opening about one-half the size of the lower incision, and the abdominal and uterine wounds were separated by the contraction and involution of the uterus. Another advantage was that the uterine incision was made through a part of the organ away from the larger blood vessels, and hence there was less danger of hemorrhage, and he believed also a portion of the uterus was less likely to rupture in subsequent labors. For protecting the intestines and to absorb any fluids which were likely to overflow, one or two gauze pads, six inches wide, six or eight feet long, were useful. It had been said that cesarean section had caused a considerable number of ruptured uteri. He could safely say that timely cesarean section would prevent most, if not all, ruptures.

Dr. CHARLES N. SMITH of Toledo said that he had done 23 abdominal cesarean sections. Two of these were done in the presence of placenta prævia centralis, one of them particularly for that sole indication and the other in the presence of transverse presentation in a woman who had lost 3 children previously in labor and who solicited this cesarean section. The first case was a woman, 20 years of age, who was seen at St. Vincent's Hospital, having had a profuse hemorrhage. She was a primipara, with a very small vagina, long, conical, rather firm cervix, with not much dilatation, and placenta prævia centralis. He did immediately an abdominal cesarean section and saved the mother and child. The second case was a woman, 32 years of age, on whom he did cesarean section last May. She had been confined previously at three different times, once with a transverse presentation and the others with breech presentations. In the transverse and one breech presentation, the child was delivered dead. In a third breech presentation the child lived for some few moments only. If she had a head presentation it was thought best to deliver by forceps. If she had an irregular presentation, or if there were any complications which led him to believe she could not be safely delivered of a living child, cesarean section must be done. Arrangements were made to take her to the hospital to have this operation done. She was taken with slight pains and profuse hemorrhage in the night, and he was quickly notified and called to see her. He found her with very little pain, with dilatation of about an inch, the head in the left iliac fossa, the back and occident anterior and the placenta seemingly occupying the entire lower segment of the uterus. She was breathing rather profusely, although the pains were not hard. She was taken at once to the hospital; he did a cesarean section, delivered her of a living child, and saved her life. He had in this particular case what he held to be the proper indications for cesarean section for placenta prævia and some other indications.

Dr. JAMES A. HARRAR of New York said he had had the pleasure of seeing Dr. Davis do a great many cesarean sections, and there was no operation that he did more smoothly than a cesarean section. At the New York Lying-In Hospital they all followed his technique. The speaker had operated on 23 cases by cesarean section, following Dr. Davis's incision, with perfect satisfaction.

Dr. H. G. PARTRIDGE of Providence said he had never seen a cesarean section done for placenta prævia. He had seen cases of placenta prævia that showed a long, rigid cervix, but these were very few. Practically all the cases he had seen had a soft, boggy, easily dilatable cervix, and within his own personal experience there had been no case which would have been suitable for cesarean section. Within a week they had a case in the Lying-In Hospital in Providence which was ideal for vaginal cesarean section. This operation was done, the mother being in good condition afterward, but the baby was born dead.

Dr. E. GUSTAV ZINKE of Cincinnati said there was no doubt in his mind that the majority of cases of placenta previa could be relieved successfully, both mother and child, by the Fry method or the De Lee method, by balloon dilatation or even by metal dilatation, although he had very little use for the latter. When we were able to watch these cases and had them in surroundings that were aseptic in character, we should see what we could accomplish by way of artificial dilatation and deliver *per vias naturales*, but when we had a case of placenta prævia

centralis, for instance, which was usually complicated by an oblique or transverse presentation, the tampon would do no good, and before one succeeded in dilating the uterus successfully, either by the tampon, balloon, by manual or metal dilatation, the woman was usually so exsanguinated that if she did not die during the process of delivery she would soon die after delivery, and the child, as a rule, was lost under these circumstances because it meant version of the aftercoming head. Besides, in primiparous women with these oblique presentations he would not attempt anything except a cesarean section. There were cases of marginal and lateral placenta prævia in which the hemorrhage was sometimes exceedingly difficult to control, and these were the cases in which a pathological condition pertained, in which the placenta was so implanted within the uterine wall that it had taken up much of the uterine musculature. Under normal circumstances the uterine wall was the same in every part, even under the placental site. Ordinarily the placenta did not occupy the muscularis at all, but only the serotina. In those cases the hemorrhage was not very excessive and it could usually be controlled; but when the placental tissue and villi had buried themselves into the musculature, then there was trouble in controlling the hemorrhage, and a timely cesarean section would save both mother and child, while with the other manipulations we would probably have a fatal result so far as the child was concerned, and in many instances the mother was not saved. No man had a right to make a cesarean section who was not thoroughly familiar with the technique of the operation. Every case of placenta prævia was a surgical one from the start and belonged to the hospital as truly as a case of appendicitis or any other surgical case, and there was no reason why these patients should not be sent to the hospital, even though the hospital might be ten, twenty or fifty miles away.

Rupture of the Symphysis Pubis in Labor.—Dr. Henry Enos Tuley of Louisville said that careful research showed that there was but one case in 30,000 to 60,000 births, including spontaneous and traumatic varieties. While recent writers stated that there were about 150 recorded cases in literature, these figures could not be verified, and Kayser's estimate of about 130 cases, plus those since recorded, would indicate that the more correct estimate was about 140. It might be safer to state that the estimate varied from 140 to 150. It had long been the teaching that the articulations of the pelvis became softened and relaxed during gestation on account of the secretion from the synovial membrane lining their surfaces. The extent to which this softening occurred was not stated by the authors who referred to this phenomenon. He did not think it was so great as to cause difficulty in standing or walking in very many cases, at least such a condition had never been brought to his attention. The percentage of cases of ruptures which were caused spontaneously varied much according to different authors. Complications might occur in the form of rupture of the anterior vaginal wall, rupture of the bladder, severe hemorrhage from rupture of the veins about the vestibule, or suppuration of the joint or soft parts. After reviewing the literature, he reported a case of rupture of the symphysis pubis in labor occurring under his observation.

Conditions Complicating Pregnancy, Labor and the Puerperium.—Dr. Asa B. Davis of New York reported a case of threatened abortion, third month, due to myofibroma in the posterior wall of the uterus. There was uterine pain and bleeding. Myomectomy was resorted to, with uneventful recovery. Pregnancy continued, with normal delivery at term. A second case was one of acute dilatation of the stomach, in which there was great physical exhaustion, and prolonged labor due to ventral fixation of the uterus. There was low forceps delivery, marked dilatation of the stomach. Recovery followed. The third case was one of intermittent and unilateral chyluria complicating pregnancy and the puerperium. The pregnancy at the eighth month was complicated with double pneumonia; recovery. Normal delivery occurred.

Conservatism in Operations for Acute Inflammatory Pelvic Disease.—Dr. Budd Van Sweringen of Fort Wayne said that one should not allow a large pelvic exudate or a tuboovarian abscess to remain until absorbed, as it meant chronic invalidism. Pus should be evacuated as soon as it was safe to do so. But when once inside the abdomen for this purpose it was wrong to think that all pathology present must be removed with the knife. Ample provision for drainage and the ablation of the original focus would be sufficient and would save many a tube and ovary which would result in much greater peace and happiness to the patient. Illustrative cases were reported.

The Significance of Hematuria and Its Management.—Dr. J. Garland Sherrill of Louisville stated that according to its causation hematuria was classified as (1) traumatic, including accidental injury and also the minor traumatism resulting from stones. (2) Inflammatory, including acute nephritis, chronic inflammatory affections of the kidney, tuberculosis, acute and chronic inflammation of the pelvis of the kidney, ureter, bladder, prostate, and also of the urethra. (3) Vascular, blood, dyscrasia, such as hemophilia, etc., nevi, venous obstruction of the kidney, varicosity of the vesical veins, especially that due to prostatic engorgement. (4) Chemical, in which class should be placed hemorrhages from irritating drugs, as turpentine, cantharides, etc. (5) Toxic, in which the hemorrhage was the result of vascular changes occurring in severe toxemias, such as those resulting from malaria, acute yellow atrophy of the liver, yellow fever, scurvy, etc. (6) Neoplastic. (7) Parasitic. Renal hematuria was probably the form most interesting to the surgeon. Laceration of the kidney, gunshot and stab wounds, frequently caused hemorrhage which appeared in the urine. Tuberculosis of the kidney presented in hematuria as an early symptom the amount of blood varying very greatly in different cases. In the treatment of hematuria, rest was of the greatest importance, and he advised the use of turpentine in small doses. Calculus, tumors, major traumatism, and unilateral tuberculosis would demand operative intervention.

Acute Unilateral Hematogenous Nephritis.—Dr. Curtis S. Foster of Pittsburgh stated that in the acute cases, with multiple miliary abscesses, and from which an overwhelming toxemia resulted, nephrectomy must be the operation of choice if we would save the patient's life. Of the 14 cases of this type encountered by Brewer 2 were untreated, and in 4 nephrotomy with drainage was done. They all died. The remaining 8 were treated by nephrectomy with recovery in each case. In the acute diffuse inflammation of the kidney the treatment was not so well defined and must depend more on the course of the disease in the individual case. In those cases where the areas of infarction were very numerous, to such an extent that the function of the kidney was seriously impaired, and when the toxic symptoms were very pronounced, nephrectomy should be the operation of choice. In cases where the infarcts were few in number, the toxemia was mild, and the general condition of the patient was good, splitting of the capsule with drainage of the diseased areas should be considered. Cases were on record, however, in which the symptoms had recurred after this operation and in which a subsequent nephrectomy was necessary.

The Diagnosis and Therapeutic Value of the Renal Catheter.—Dr. K. I. Sanes of Pittsburgh said that the value of the ureteral catheter in the diagnosis and treatment of urological disease was well established. It behooved us all to make use of it more frequently than it had been our custom in the past. To some of us ureteral catheterization seemed a difficult procedure; to others a dangerous one. It should be neither dangerous nor difficult in the hands of men practising surgery. Those who had catheterized many hundreds of ureters have learned not to fear infection from its use, and had gradually extended the field of its application with great satisfaction to themselves and great benefit to their patients.

Renal and Ureteral Calculi.—Dr. Henry Dawson Furniss of New York said that renal and ureteral calculi were more frequent than was generally supposed, and often existed, especially calculi, in the renal cortex for a long time without symptoms. The classical text book symptomatology of calculi was oftentimes associated with other conditions of the urinary organs. The effect upon the kidney of calculi was dependent upon the size, shape, character, and most of all the location of the stones, those in the pelvis of the kidney and the ureter causing most damage. For those calculi that could not be attacked from the vagina or bladder, the best procedure in stones that would be difficult to locate was the combined intra and extraperitoneal operation. If they could be easily found on account of their size he would prefer the extra peritoneal route. It was not necessary to close the ureter, as it healed rapidly. A cigarette drain near the ureter had best be used for 72 hours, or while there was still drainage. If the stones were to be felt through the vagina they could be removed through it; if impacted in the vesical orifice, by slitting the ureter through an operating cystoscope, or after suprapubic cystotomy, or by cautery fulguration.

Local Anesthesia in Abdominal Surgery with Cinematographic Demonstration.—Dr. Julius H. Jacobson of Toledo stated that with this method of local anesthesia he had performed 36 operations upon 28 patients, 8 of these being operated for double hernia. The operations were

as follows: 28 operations for radical cure of inguinal hernia, 3 operations for strangulated inguinal hernia with radical cure, 1 operation for radical cure of femoral hernia, 2 operations for strangulated femoral hernia, 1 operation for incarcerated umbilical hernia, 1 operation for incisional hernia, total number of operations on 28 patients, 36. Mortality nil. In only two of the earlier operations was it necessary to finish the operation under a general anesthetic. This was due to inexperience with the method. The operations were uniformly painless, without nausea or vomiting, and without the slightest toxic effect from the anesthetic solution. The sensation of the operation was described by the patients as that of a pulling or tugging on the parts. In a few instances some pain was complained of when working about the hernial sac or peritoneum. This can be overcome by a separate injection of the neck of the sac early in the operation. As the adrenalin acted as a hemostatic, there was some danger of a postoperative hematoma. It was therefore necessary to ligate all blood vessels as soon as they were divided Cinematographic demonstration showed the complete operation for inguinal hernia under local anesthesia, demonstrating the method of injection, the operation being of the Ferguson type. Motion pictures of local anesthesia of double inguinal hernia, umbilical hernia and strangulated inguinal hernia were shown.

Operative Treatment of Mammary Carcinoma, with Special Reference to the Pectoral Muscles and Auxiliary Space.—Dr. CHARLES EDWARD RUTH of Des Moines said the principal object of his paper was to eliminate all complications resulting from operations upon the mammary gland in malignancy which emptied the axillary space of everything but its vessels and nerves, and thereby exposed them to the grasp of cicatricial tissue which must fill in and close the space, and in 31 per cent. of cases caused edema of the arm, and many times intolerable pain with, in no small proportion, practical loss of function of the arm. The operative plan outlined in the paper proposed to eliminate these difficulties by the use of the distal part of the pectoral muscles sutured against the chest wall in such manner as to eliminate entirely all dead space, cicatricial formation, contraction, edema, and give a result which left little or no impairment of function in its range, and in no manner increased the danger of recurrence of the malignancy.

Diagnostic Hysterotomy.—Dr. GORDON K. DICKINSON of Jersey City stated that it was yet a question as to when hysterotomy was justifiable. He had grave doubts whether anyone could answer this question in pathological terms. One's personal pride in making a diagnosis without too much surgery should lead to a proper effort to obtain the same through a complete history, curettage, and perhaps the added opportunity of a manual examination of the uterus, but if by these means, particularly in chronic cases, one could not be positive as to the contents of the uterus or of the condition of its substance, then in his opinion hysterotomy was not only justifiable but necessary.

The Use of Iodine in Abdominal Surgery.—Dr. LOUIS FRANK of Louisville read a paper on this subject, in which he drew the following conclusions: From our work, not only experimentally, but from our clinical observations with iodine in the preparation of the field for abdominal operations, we would conclude that while it was effective as a means of sterilizing the skin it had its disadvantages. First, should the intestines come in contact with the iodine, adhesions would undoubtedly take place in the area thus exposed, due to the action of the iodine as an irritant to the peritoneum. Second, when it was used as a means of preparing the field, the utmost care should be taken to avoid such contact by protecting the field beyond the abdominal incision by means of moist pads securely fixed in place. Third, tincture of iodine, judging from experience and experiments, should never be poured into the abdomen.

Dr. JOHN W. KEEFE of Providence, R. I., read a paper on stenosis of the pylorus in infancy, and reported several cases.

Dr. ARTHUR T. JONES of Providence, R. I., reported three cases. One of these was a case of solid tumor of the parovarium, evidently originating from the Wolffian body. Case 2 was one of large sarcoma of the ovary, with a great amount of fluid in the abdominal cavity. There had been improvement in the general condition of the patient since operation. The prognosis was good for several years in this type of case. In Case No. 3 he detailed the results three years after hysterectomy in a case of sarcoma and carcinoma of the uterus.

Sudden Severe Hemorrhage Into an Ovarian Cyst Following Delivery.—Dr. WILLIAM EDGAR DARNALL of Atlantic City stated that ovarian tumors of all sorts and especially cysts, almost always produced serious trouble sooner or later, and especially during pregnancy and the puerperium. The most dangerous period was the puerperium. It was the part of wisdom, therefore, to remove them as soon as they were discovered, if possible.

Cholangitis and Pancreatic Lymphangitis.—Dr. L. W. SWOPE of Pittsburgh reported 22 cases out of a series of 2000 operations on the biliary and pancreatic systems. The clinical histories and physical signs justified the diagnosis of carcinoma of the head of the pancreas. The findings were of such a nature that differentiation from cancer was almost impossible. There was recovery with relief of symptoms after temporary or permanent drainage of the bile passages which excluded the possibility of malignancy. At autopsy on the three cases that died the postoperative and postmortem changes were so marked that the characteristic operative findings were completely altered; consequently postmortem examination had added very little to our knowledge of pancreatic lymphangitis. It was probably that the infection causing the pathologic enlargement of the head of the pancreas in these cases traveled through the lymphatics, causing lymphangitis in the pancreatic interstitial tissue. This supposition explained the improvement and cure with the subsidence of the inflammatory enlargement of the head of the pancreas which followed operation. The origin of infection was often obscure. Treatment consisted in drainage of the bile passages, temporary or permanent. The former was obtained by surface drainage of the gall bladder and common duct, the latter by anastomosing the gall bladder to the duodenum or stomach.

Observations Based on Seventy Cases of Bowel Obstruction with Special Reference to the Unusual Cases.—Dr. WALTER C. G. KIRCHNER of St. Louis reviewed his own cases of intestinal obstruction and gave an abstract of the histories of the unusual cases. Obstructions due to hernia were encountered in 47 cases, or in 10 per cent. of the hernias operated upon. Most of the cases of ileus were seen in the critical stages, and the mortality rate was 52 per cent. In the 70 cases postoperative ileus due to adhesions occurred 10 times, with a mortality of 50 per cent. The appendix was implicated in 8 per cent. of the cases. Resection of bowel was performed in 25.7 per cent. of the cases, with a mortality of 27 per cent. The intestinal obstructions which were encountered were those caused by adhesions, carcinoma, fibromyoma, intussusception, volvulus, interstitial hernia, excessive dilation of the colon, gall stone, prolapse of intestines through rupture in mesentery, prolapse of intestine through a rent in the omentum, thrombosis of the superior mesenteric artery, etc. Obstruction of the bowel was essentially a surgical condition, and the mortality rate was in direct proportion to the duration of the obstruction. Greater stress should be laid on the necessity for early operation in bowel obstruction. In the early cases of obstruction, resection might be a safe procedure, while in the critical cases primary enterostomy and later resection of bowel or repair of fecal fistula was a better course to pursue.

Cancer of the Uterus and Fibroid Tumors from a Clinical Standpoint.—Dr. EDWARD JOSEPH ILL of Newark said that from personal experience he held that fibroid tumors were not a cause of malignant degeneration of the uterus. Among 443 operative cases in his hands there was no record of any fibroid having undergone malignancy, nor was there any record among 2,600 cases recorded in his office case book of any having undergone malignancy, although many of these cases were seen repeatedly for years. The autopsy records of hospitals variously situated showed that from 4 to 8 per cent. of all women over 30 years had fibroid tumors. During the same time that the 443 operations of fibroid tumor took place he operated on 175 cases of cancer of the uterus. Five of these cases had fibroids in the uterus, 4 were cases of true carcinoma, one case, a sarcoma, had small fibroids in the posterior wall, while the sarcoma was situated in the anterior wall behind the scar of an old fixation operation. It was thus shown that all his cancer cases had but 2.8 per cent. of fibroids, which was less than the average of all women over 30 years. His deductions were that we had no right to suggest the operation for removal of fibroid tumors when possible future malignant degeneration constituted the only indication.

The Later Operative Technique in the Treatment of Cancer, with Special Reference to Cancer of the Breast and Uterus.—Dr. MAURICE I. ROSENTHAL of Fort Wayne said it was just as important that the surgeon should appreciate the high degree of infectiousness of cancerous tissue as it was that the practitioner should recognize any symptom which was significant of this disease. The radical operation had demonstrated that infiltrations and

glandular enlargements, apparently cancerous, were frequently inflammatory in character, and that cases apparently inoperable by reason of such extensions, were readily operable by this technic. As a result of this greater operability, the primary mortality following this greater technic must be considered when estimating its true value. With the exception of certain epitheliomata it was in cancer of the breast that something like a reasonable result from operative procedure for cancer was obtained. With some little changes in the technic of this operation, which he described in detail, he had obtained results which, compared with cancer in other regions, might almost be called satisfactory. We might take the technic of this operation, which embodied all that went to make up the operative technic of this disease as a technic typical for operation for cancer in other organs. In his paper he pointed out such steps in the technic as would have a tendency to make the operation more successful, and then reported a series of cases on which he had operated with the results.

Uterine Fibromyomata of the Lower Uterine Segment.—Dr. James N. West of New York reported three cases. The points of interest and instruction in these cases were so numerous that he only called attention to the following: 1. Cases of fibroid tumors of the lower uterine segment occurred with moderate frequency where operation was an immediate and urgent necessity on account of pressure upon the urethra. 2. Cases occurred where fibroids in the lower segment complicated by inflammatory conditions closely resembled malignancy, and that such cases should have the benefit of an exploratory incision. 3. A preliminary myomectomy might often allow the structure to assume a more normal anatomical relation and thus simplify operation and reduce the dangers.

Laceration of the Cervix; a Causative Factor in Salpingitis.—Dr. Francis Reder of St. Louis stated that the disclosure of a vaginal examination did not prove definitely the existence of a salpingitis, because the examining finger could not interpret correctly the pain that pervaded hypersensitive pelvic viscera. The existence of a hydrosalpinx, when sufficiently large, can usually be diagnosticated by palpation without difficulty, whereas a tube that was slightly or not at all distended with fluid would present its difficulties. In a woman who had given birth to children the most frequent lesion that could be directly attributed to childbirth was a laceration of the cervix. It was a trauma whose importance had been not only too often disregarded, but it had also been underestimated. If the tear was a superficial one, it would most likely heal completely in a short time. If, however, the laceration was a deep and perhaps extensive one, it would not heal. Eversion of the traumatized lips of the cervix would take place, and a chronic inflammatory process with its sequelæ would become established. That lacerations of the cervix were the most common atria for infection of the tubes was evidenced by the frequency with which this pathology was encountered during operation. Not only was the infective material carried by the cervical lymphatics to the tubal structures, but it was also deposited into the cellular tissues of the broad ligaments. The necessary surgical measure for relief consisted in freeing the fimbriated end of the tube, turning back the mucosa and suturing it. Of equal importance was the obliteration of the primary focus by plastic repair of the lacerated cervix. The source inviting microbic inflammation having been removed, infective material would no longer find routes of transmission to the tubes. Freedom from these continued bacterial assaults would gradually permit the tube to return to a normal or almost normal state, with the possibility that the patient might again become pregnant.

Notes on Adventitious Tissues of the Abdominal Cavity.—Dr. Robert T. Morris of New York said that the Lane kink, Jackson's membrane, cobwebs of the attic, and other adventitious tissues of the abdomen depended upon hyperplasia of embryonic structures already present. The hyperplastic change was brought about by toxic as well as mechanical influences. These tissues were to be differentiated from the adhesions dependent upon toxic injury of endothelial structures. A simplified operation for short circuiting the bowel was described.

Gallstone Surgery.—Dr. Joseph H. Branham of Baltimore reported 7 cases, two of which showed the danger of long continued gall stone diseases as causing carcinoma. The cases demanded cholecystectomy. In case where the gall bladder was not hopelessly diseased, and where there was no stricture, he had done cholecystostemy. These cases had recovered and usually had remained well. One of his cases had a fistula of long duration which failed to yield to the usual treatment. She fell into the hands of another physician who closed the fistula with electrocautery. He found the same thing effectual in another case after other methods had failed. He was persuaded that the gall bladder would be removed more frequently in the future than in the past. The Mayos, who, on account of their enormous experience and wonderful success in these conditions, had done much towards making cholecystotomy the operation of choice. They pointed to the slightly greater mortality of cholecystectomy. This might be accounted for by the graver conditions in which it had been done. They also pointed out that the gall bladder was too small to act as a reservoir, but that probably its function was to relieve tension during the height of liver secretion, and thus prevent regurgitation of bile into the pancreatic duct. This was an ingenious theory, yet many animals got on without this organ. Was it not more probable that the small inadequate gall bladder of man, with its poorly developed coats, was a disappearing organ, physiologically as well as pathologically, very like the appendix?

A Review of the Plastic Methods of Closing the Incisional Herniæ.—Dr. Lewis Frederick Smead of Toledo stated that the earliest operations for ventral hernia closed the ring without incising even the skin. Later all useless tissue down to the peritoneum was removed and the edges of the ring alone drawn together. Still later the edges of the ring were inverted and the anterior surface of the fascia approximated. Following this, the rectus sheath was opened and the abdominal wall closed in layers. Omphalectomy was not generally used until after 1888, and the lateral method of approaching the hernial ring was suggested in 1891. Numerous plastic methods of using the fascia and muscle to close the rupture were devised, but the principle of overlapping from above downward had displaced most of them. Tension sutures were used, the hernial ring was attached from within the abdomen, and numerous foreign materials inserted to close the opening, and many important general principles were laid down. At present the closure in layers or the Mayo operation was used in small hernias, but in the larger ones, if some plastic device was not practicable, we relied upon the filigree. The transplantation of fascia might take the place of the filigree in time and was at present a valuable means of reinforcing doubtful suture lines.

Papers were also read by the following members: "Fibroma Cardia in a Girl of Eighteen; Gastrostomy and Enucleation," by Dr. John F. Erdmann, New York City; "Appendicitis in Young Women," by Dr. H. S. Lott, Winston, S. C.; "A Seven Pound Ovarian Tumor That Developed in Nine Days," by Dr. J. H. Carstens, Detroit, Michigan; "Omentocolopexy," by Dr. H. W. Longyear, Detroit, Michigan.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Charles N. Smith, Toledo, Ohio; *First Vice-President*, Dr. Hugo O. Pantzer, Indianapolis, Indiana; *Second Vice-President*, Dr. J. H. Branham, Baltimore, Maryland; *Secretary*, Dr. E. Gustav Zinke, Cincinnati, Ohio, reelected; *Treasurer*, Dr. Herman E. Hayd, Buffalo, New York, reelected.

Buffalo, New York, was selected as the place for holding the next annual meeting.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Oklahoma State Board of Medical Examiners.

April, 1913.

(*Concluded from page* 644.)

OBSTETRICS AND HYGIENE.

1. When do you use ergot in obstetrical practice, and for what purpose?

2. Give in their order the three most common presentations.

3. How long can the child live before delivery with the placental circulation cut off? What precautions should be used to prevent compression of the cord in breech presentation?

4. What symptoms would cause you to suspect a rupture of the uterus? How would you manage a case?

5. What are the stages of labor?

6. Define abortion, miscarriage, premature labor.

7. Define puerperal septicemia. Give diagnosis and treatment.

8. What precautions would you use to prevent inflamma-

tion of the mammary glands? Give in detail your treatment of mammary abscess.

9. Give instructions for the prevention of the spreading of typhoid.

10. Is cerebrospinal meningitis contagious? If so, how are the germs conveyed?

GYNECOLOGY.

1. Differentiate fibroid, pregnancy, ascites, fat.
2. Diagnose and treat tuberculous endometritis.
3. Give indications for and technique of operation for amputation of cervix.
4. Give indications for and technique of trachelorrhaphy.
5. Make diagram showing relation of uterus, tubes, ovaries, vagina, bladder, and rectum.
6. Differentiate pudendal hernia, abscess of Bartholin's gland, and tumor of labia.
7. Describe venereal warts. Give etiology and treatment.
8. Vulvitis. Give etiology and treatment.
9. Give indications for knee-chest posture in office treatment.
10. Give indications for use of hot vaginal douche.

SURGERY.

1. What are the varieties of ankylosis?
2. Give symptoms and treatment of fractures of the nasal bones.
and describe a method of treatment.
3. State the most common seat of fracture of the clavicle
4. Describe the treatment for fracture of lower end of the humerus.
5. Describe a modified circular amputation of the leg.
6. What are the indications for excision of the knee joint?
7. How are wounds classified?
8. Give a full description of the operation for thyroidectomy.
9. Give the indications for the removal of the mammary gland.
10. Describe an operation for circumcision.

ANSWERS.

OBSTETRICS AND HYGIENE.

1. *Ergot* is used sometimes after the birth of the head, and during the third stage of labor, to induce uterine contractions, to prevent hemorrhages; also sometimes used in amenorrhea due to plethora.

2. The vertex is the most common presentation; next to this is the breech; the third in order of frequency is either the face or the shoulder.

3. About five to eight minutes may be considered the time a child can live before delivery with the placental circulation cut off. When the trunk is delivered a loop of the cord should be placed toward that part of the pelvis where it will be least liable to pressure.

4. RUPTURE OF THE UTERUS. "When rupture actually occurs the typical symptoms are a sudden, sharp pain in the womb (caused by its tearing), sometimes accompanied by an audible noise; sudden and simultaneous cessation of labor pains; a sensation as if warm fluid (really blood) were being diffused into the abdomen; violent shock and collapse, indicated by pallor, feeble and frequent pulse, cold extremities, fainting, hurried respiration, vomiting, etc. (usually due to hemorrhage into the peritoneal cavity). On vaginal examination the presenting part of the child is found to have receded from its former situation, owing to partial or complete escape of the fetus through the rent into the abdominal cavity, where, by abdominal palpation it may be felt as an irregular-shaped, movable tumor, more or less distinct from another tumor formed by the partially contracted uterus. Blood may or may not escape from the vagina. A loop of intestine may prolapse through the rent and be found by vaginal examination."

Treatment: "After rupture has occurred, especially if it be 'complete' and extensive, and the child should have escaped, wholly or in great part, through the rent into the abdominal cavity, laparotomy should be done at once, child, placenta, blood clots, etc., being removed through the abdominal incision; the peritoneal cavity cleansed with hot saline solution; the rent in the uterus repaired by suture; or in case of an infected uterus, or one that will not contract, or in which the rupture cannot be well secured, the entire uterus should be removed." (King's *Obstetrics.*)

5. *Labor* is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with a complete dilatation of the os uteri, and ends with the birth of the child. The *third step* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

6. *Abortion* is delivery of the product of conception before the twelfth week.

Miscorriage is delivery of the product of conception between the twelfth and twenty-eighth weeks.

Premature labor is delivery of the fetus between the twenty-eighth week and full term.

7. *Puerperal septicemia* is septic intoxication with the presence of living pyogenic bacteria in the blood occurring during the puerperium. *Symptoms:* Chill; rapid rise in temperature, to about 103° or 104°, higher in the evening than in the morning; sweats; rapid pulse; depression; dry tongue; anorexia; carphologia; scanty, high-colored, albuminous urine; restlessness; sometimes delirium or coma. The uterus is large, and tender; the lochia are diminished or suppressed; the milk secretion is often suppressed; pain in the abdomen; peritonitis may develop. *Treatment:* Prophylaxis is of the greatest importance. Purgatives; vaginal douches; some recommend curettage, others decry it; the introduction of antiseptics into the uterus; supportive and general treatment are indicated; specific sera and vaccines have been recommended by some.

8. As mastitis is due to infection, the glands should be handled as little as possible, and only with clean hands; pressure should be avoided; the breast and nipple should be kept dry; engorgement should be prevented, if possible. Nursing from the affected breast should be stopped; salines should be administered; pressure, combined with hot fomentations may be employed; if suppuration occurs, incision with drainage is indicated.

9. *Typhoid fever* is preventable. All water for drinking or for washing dishes, etc., and milk should be boiled; no ice should be put in water or other drink or food; flies should be kept out of the house; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

10. "Precisely how the contagion is transferred from an infected person to a healthy one is not known, but the disease is probably contagious." (Anders' *Practice of Medicine,* 1911.) "The disease is not highly contagious, and is probably not transmitted by clothing or the excretions." (Osler's *Practice of Medicine,* 1912.)

GYNECOLOGY.

1. *Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

Ascites: Absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides, the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies with the position of the patient.

Fat: The signs of pregnancy are absent; there are none of the signs of ascites or fibroids.

2. *Tuberculous endometritis:* "Tuberculosis of the uterus has produced symptoms and physical signs something like those of cancer of the uterus, viz., discharge, hemorrhage, wasting, with enlargement of the uterus, expansion of its cavity, and roughening of its interior. Advanced tuberculosis of the uterus has been always associated with tuberculous disease elsewhere. The uterus has been fixed, and the patient has been cachectic. Operative removal of the diseased pelvic organs has been useless as well as dangerous. The disease, in its early stages, causes no symptoms. The diagnosis is to be made by finding tubercle bacilli in the discharge. *Treatment:* If primary tuberculous disease of the uterus is found out

before the disease has infected any other part of the body the treatment is to remove the uterus and Fallopian tubes. As yet this has not been done often enough to justify any broad statement as to the result." (Herman's *Handbook of Gynecology.*)

3. *Amputation of the cervix* is indicated in cases of elongated cervix and cancer of the cervix. *Operation:* "The cervix is thoroughly exposed by the introduction of the bill of a large speculum; with the sound the operator determines the position of the cervical canal and estimates the mobility of the uterus; by means of the vesical sound the precise relation of the bladder to the cervix is ascertained. The cervix is firmly grasped with a stout volsella and drawn down; with a scalpel the surgeon transversely divides the mucous membrane on the anterior wall of the cervix as high up as the bladder permits; the assistant keeps him informed of the position of the bladder by retaining the sound in the lowest part of the vesical cavity. Having divided the mucous membrane, the bladder is easily detached from the cervix by the handle of the scalpel. The knife is then carried through the mucous membrane on the sides and posterior aspect of the cervix. The next step is to secure the uterine arteries as they run to the sides of the cervix near the spot where the vaginal mucous membrane is reflected on to it. When the bladder is detached and held apart from the cervix by a retractor, while the cervix is drawn down by the volsella, the artery may be seen, and is easily secured. It is well to secure it as close to the center as possible in order to avoid the ureter. Having secured the artery on each side, the cervix may be amputated with a scalpel or with scissors. When the uterine arteries are deliberately exposed and secured there is no bleeding from the stump, but a small artery here and there in the cut edge of the vaginal mucous membrane may require to be seized or ligatured. The vagina is then douched and the patient returned to bed." (Sutton and Giles' *Diseases of Women.*)

4. Trachelorrhaphy. *Indications:* Laceration of cervix uteri; particularly when followed by subinvolution of uterus, by eversion and hypertrophy of cervix, by infection, by Nabothian cysts, by menorrhagia, leucorrhea, backache, and reflex nervous disturbances.

Operation: "The patient is anesthetized and placed in the lithotomy position, and the cervix well exposed by a speculum. The vagina is thoroughly disinfected by douching and swabbing, and dilatation and curetting are then carried out when necessary. After this the anterior lip of the cervix is seized with a volsella, and the reversible tenacula forceps introduced exactly in the middle line and the points separated. The volsella is then removed. By means of scalpel and forceps two flaps are now dissected off the exposed surface, taking care to leave a narrow strip of mucous membrane in the middle line, which will form the lining for the new cervical canal when the lips are approximated. While the surfaces are being vivified there is usually free oozing; this is useful, as it serves to deplete the cervix and diminish its volume. In many cases before operation the bulky, everted lips look as if they could not come together, yet, after depletion brought about by dissection, they can be approximated with ease. When the flaps have been dissected off, the tenacula forceps are removed, the lips of the cervix are allowed to fall together, and the forceps are then reapplied in such a way as to hold them in apposition. Care must be taken to secure the cervix in the middle line. A curved needle is used to introduce the sutures: the best material is silkworm gut, and, if secured by means of shot and coil, their subsequent removal is greatly facilitated. Three or four sutures should be placed on each side, and those nearest the middle line should be about one centimeter apart. The tenacula forceps are now removed and a sound is passed into the uterus, to make sure that the cervical canal is free. The parts are then carefully dried, and the vagina lightly packed with iodoform gauze."

6. *Pudendal hernia* gives tumor with pulsation or coughing, and is possibly capable of reduction.

Abscess of Bartholin's gland gives local redness, swelling, pain, heat, and febrile symptoms.

Tumor of labia gives swelling, without the other symptoms mentioned above.

7. Venereal warts. "They grow very rapidly and attain to the size of a fist or even larger. The warts are single or multiple, pedunculated or sessile, and in some cases they form large masses of excrescences resembling cauliflowers, cockscombs, bunches of grapes, or mulberries. Their color depends upon the vascularity of the growth and the condition of the epidermis. If the epidermis is present and the surface is dry, their color is the same as that of the surrounding skin or mucous membrane; but if the warts are more vascular than normal and the epidermis is removed by friction or maceration, they are of a deep red or purple hue, and the secretions are purulent, offensive, and highly irritating. Condylomata are situated on any part of the vulva, around the anus, on the inner surface of the thighs, and also on the vaginal wall. *Causes:* Venereal warts are due to irritating discharges, want of cleanliness, and the congestion and leucorrhea of pregnancy." *Treatment:* Excision of wart by curved scissors, followed by cauterization; application of calomel and salicylic acid; cleanliness; douches; and tonics. (From Ashton's *Gynecology.*)

8. Vulvitis. *Etiology:* Gonorrhea, dirt, obesity, pessaries, or other foreign bodies, vaginal fistulæ, irritating urine, excessive coitus or masturbation, syphilis, chancroids. *Treatment:* Where possible, remove the cause; rest; cleanliness; mild alkaline douches; antiseptic solutions; salines; anodynes.

9. *Knee-chest posture* is employed (in office treatment) for the replacement of a retroverted uterus, or of a prolapsed uterus or appendage; or for insertion of tampons in the vagina.

10. *Hot vaginal douche is indicated:* In chronic pelvic inflammations; in uterine hemorrhage; for cleanliness. In obstetrical practice, a hot vaginal douche is given: (1) By some practitioners, as a routine treatment after every case of labor; (2) by others only when there have been repeated vaginal examinations, or (3) in case of foul lochia; (4) when there has been some operative procedure; (5) in case of sepsis.

SURGERY.

1. *Ankylosis* is (1) true or bony; (3) false or fibrous.

2. Fracture of nasal bones. *Symptoms:* Displaced or flattened nose, which is soon marked by swelling; crepitus may be present; nose breathing is difficult; emphysema and epistaxis may be present. *Treatment:* External pressure aided by padded forceps in the nostrils; plugging of the nostrils; a moulded gutta-percha splint fixed over the nose by a bandage; sometimes a Mason pin is required.

3. The most common seat of fracture of the clavicle is just external to the middle, at the junction of the two curves.

Sayre's method for fractured clavicle: "Sayre's dressing consists of two strips of adhesive plaster three and a half inches wide and two yards in length. The first strip is looped around the arm just below the axillary margin and is pinned or sewed with the loop sufficiently open not to constrict the arm. The arm is then drawn downward and backward until the clavicular portion of the pectoralis major muscle is put sufficiently upon the stretch to overcome the action of the sternocleidomastoid muscle, and in this way draws the sternal fragment of the clavicle down to its place. The strip of plaster is then carried completely around the body and pinned or stitched to itself on the back. The second strip is next applied, commencing on the front of the shoulder of the sound side; thence it is carried over the top of the shoulder diagonally across the back, under the elbow, diagonally across the front of the chest to the point of starting, where it is secured by pinning or sewing. A slit is made in this strip to receive the point of the elbow. Before the elbow is secured by the plaster it should be pressed well forward and inward." (Wharton's *Minor Surgery and Bandaging.*)

4. *Treatment of supracondyloid fracture at the lower end of the humerus:* "The supracondylar fracture is reduced by first extending the elbow to free the lower fragment from the triceps, and then, while making traction through the forearm, manipulating the fragments into position, and finally flexing the elbow to an acute angle and supinating the forearm. In this way the triceps is put upon the stretch and forms a natural posterior splint. A layer of wadding is placed in the bend of the elbow to separate the opposed skin surfaces, the elbow fixed in this position by means of a figure-of-eight bandage, and the arm placed in a sling so arranged as to support the elbow. According to Robert Jones this position should be maintained for four or five weeks, the part being examined periodically to make sure that the bones remain in position. Movement and massage should then be begun. Except in compound injuries operative treatment is rarely called for in recent cases." (Thomson and Miles' *Surgery.*)

5. *Modified circular amputation of the leg:* "Cut semilunar skin-flaps, lay them back, and cut circularly to the bone at the edge of the turned-up flap. Another method of modified circular amputation is by adding to the circular cut a vertical incision down the front of the leg.

In sawing the bones of the leg the surgeon, who stands to the outer side of the right leg or to the inner side of the left leg, divides the fibula first, and at a higher level than the tibia, and bevels the anterior surface of the tibia. In sawing the left fibula the saw points to the floor; in sawing the right fibula it points to the ceiling." (Da Costa's *Surgery.*)

6. *Indications for excision of the knee-joint:* Tuberculosis of the knee, some compound fractures and compound dislocations, and in some forms of ankylosis.

7. *Wounds are classified,* as:

I. Contused and open wounds.

II. Open wounds may be: Incised, lacerated, contused, punctured, gunshot, or poisoned; also penetrating and perforating.

III. Aseptic and septic.

8. *Partial thyroidectomy* is conducted as follows: An incision is made over the most prominent part of the tumor, either along the lower third of the anterior border of the sternomastoid, or transversely across the neck in order that the scar may be less visible. The platysma and deep fascia are divided, and the sternomastoid, sternohyoid, sternothyroid, and omohyoid drawn aside, or, if need be, divided. The lobe to be removed is thus exposed within its capsule, which should not be opened. The limits of the mass are defined by the finger or a blunt dissector, and the vessels entering or leaving it are secured. The superior thyroid vessels are doubly ligatured and divided at the upper end of the growth, the middle thyroid vein is secured at the middle of its outer border, while the inferior thyroid vessels are dealt with below, special care being taken to avoid the inferior or recurrent laryngeal nerve by tying the vessels as near to the gland as possible. The lobe is now freed from the underlying structures, as also, if need be, the isthmus from the trachea. In detaching the latter, the surgeon must not forget that the cartilaginous rings may have been absorbed, and that the walls of the trachea, being then merely fibrous in nature, are easily wounded. The isthmus is divided, and any bleeding vessels secured; or, if necessary, it may be ligatured before division. The wound is closed by buried sutures for muscles and fasciæ, and a Halstead's intradermic stitch for the skin. A drainage tube may be required for twenty-four hours, as it is difficult to employ much pressure on the neck. Healing by first intention should be the invariable result, and the scar almost invisible." (Rose and Carless' *Surgery.*)

9. *Indications for removal of mammary gland:* Enormous hypertrophy, Paget's disease of the nipple, epithelioma of the nipple, carcinoma, sarcoma, cystic adenoma, diffuse tuberculous or septic disease if breast is riddled with sinuses.

10. "*Circumcision* is performed by drawing the prepuce forward and then enclosing it in a pair of clamp-forceps placed obliquely just in front of the glans. The prepuce is next divided with a straight bistoury, and the forceps removed, when the skin and mucous membrane retract. The mucous membrane, if adherent, is dissected loose from the glans; if redundant, it is trimmed with scissors to make it correspond to the line of skin incision; the cut edge of the mucous membrane is next fastened to the cut edge of the skin by a few sutures of silk or catgut." (Wharton's *Minor Surgery.*)

Paroxysmal Cough from Irritation of Chorda Tympani Nerve by a Spicule of Steel.—J. Donelan reports the case of a man, aged 45, who some days after visiting the engineering works of a railway company was attacked by a violent fit of coughing with a feeling of discomfort along the left side of the tongue. This symptom constantly recurred on apparently no provocation from any ascertainable cause for two years. His larynx, except for a general hyperemia, probably due to the cough, was normal. Nothing could be found in the cervical or thoracic regions that accounted for it. He had been repeatedly examined by various medical authorities. The author made a similar examination without result until he inspected the ears as part of a routine method. The right ear, meatus and tympanum were normal. So were the left, except for a tiny black spot with a reddish areola around it. This was situated just behind the malleus at exactly the spot where the chorda tympani nerve crosses it. Cocaine was applied, and a small spicule of steel about 3 millimeters long was extracted. The patient had a most violent fit of coughing then, but according to the last report of the attending physcian a few months ago he has had no further return of his trouble.—*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

The Treatment of Whooping Cough.—Althoff recommends the following mixtures:

℞ Infusion of ipecac root, 0.3 gram in 170 c.c. of water.
Antipyrin,
Sodium bromide, of each, 2 grams.
Heroin hydrochloride, 0.01 gram.
Syrup of althea, ad 200 grams.

M. et S.: One teaspoonful to one-half a tablespoonful every three hours, according to the age of the child.

℞ Antipyrin,
Sodium bromide, of each, 2 grams.
Heroin hydrochloride, 0.006 to 0.01 gram.
Distilled water, ad 100 c.c.

M. et S.: One teaspoonful to one-half a tablespoonful, in milk, every two or three hours, according to the age of the child.

℞ Aristochin, 0.05 to 0.1 gram.
Milk sugar, 0.5 gram.

This dose is to be given in powder form three times a day to a child less than one year of age. In older children the dose of aristochin may be as large as 0.3 gram.

Intravenous Injections of Ergotin in the Treatment of Hemoptysis.—M. Garmagnano first determines the patient's blood pressure. If this is less than 110 he gives an intravenous injection of 0.50 gram of ergotin dissolved in 1 c.c. of distilled water. If the blood pressure is higher than 110 there is injected in addition 0.001 gram of morphine hydrochloride. A few minutes after the administration the cough and hemoptysis cease.—*La Riforma Medica.*

Chloroform as a Vermifuge.—The following is an old prescription for tapeworm:

℞ Chloroform, 4 grams.
Castor oil, 20 grams.
Gum arabic, 10 grams.
Orange-flower water, 20 grams.
Distilled water q. s. ad 150 c.c.

This should be taken in four portions at half-hour intervals.

The Treatment of Phthiriasis Complicated with Impetigo in the Child.—One of the many parasiticides may be used. None is better than a mixture of equal parts of olive oil and kerosene oil, applied at night and washed off with soap the next morning. If the parasites are particularly numerous Sabouraud recommends the following:

℞ Pure vaseline, 50 grams.
Pure xylol, 100 drops.

If the pediculosis itself has been controlled one may then treat the impetigo with one of the following ointments:

℞ Subacetate of lead, 1 gram.
Vaseline, 30 grams.

℞ Powdered camphor, 0.50 gram.
Powdered boric acid, 1 gram.
Zinc oxide, 6 grams.
Lanoline, 6 grams.
Vaseline, 10 grams.

℞ Yellow oxide of mercury, 2 grams.
Zinc oxide,
Lanoline,
Vaseline, āā 8 grams.

℞ Zinc oxide, 2 grams.
Calomel, 0.20 gram.
Vaseline, 20 grams.

A CASE OF PSEUDOBULBAR PARALYSIS.

PRESENTING FACIAL SPASTIC MOVEMENTS SIMULATING LAUGHTER.

BY BERNARD OETTINGER, M.D.,

DENVER, COLO.

NEUROLOGIST TO THE HOSPITAL FOR THE CITY AND COUNTY OF DENVER AND ST. ANTHONY'S HOSPITAL.

THE accompanying cuts depict with some fidelity a condition that I do not remember to have seen described in any American journal. The clinical description of the case is as follows:

R. H., aged sixty-four years, a blacksmith, three years ago fell while sitting in a chair. He says he did not become unconscious. Following this single apoplectic attack he could not use his left arm and leg; speech disturbances were present; also, the facial spasms hereinafter detailed. Attempts to obtain many particulars of the anamnesis were abandoned for several reasons. H. replies only to the simplest questions; it is difficult to understand what he says; and, finally, the physical examination suffices to develop the material facts. Physical examination: The patient is tall and of large frame. The extremities are thin, the skin dry and below both knees eczematous. He has never had smallpox. A number of circular and oval scars symmetrically rounded suggests a sometime syphilitic infection. This is confirmed by a positive Wassermann. Face: The expression in repose is intelligent, showing at this time only the imprint of a left hemiplegia. The ocular bulbs can be moved in all directions. The pupils react to light and to accommodation, although sluggishly. No hemianopsia. The skin of the forehead can be wrinkled and the eyes forcibly closed, but the left eyebrow and lids are at a lower level than on the right side; also, the mouth droops and the lower lip is noticeably turned out on the left side. The nasolabial fold is more pronounced on the paralyzed side. When requested, the teeth are shown. At this time when the mouth is volitionally widened the left side lags. The lower jaw can be drawn from side to side. The tongue can barely be extended beyond the teeth but has adequate range in a side-to-side movement. On the left side, half an inch from the tip, the tongue is deeply notched. When the chin is tapped on the right side a marked jaw jerk is elicited; a like reflex is absent on the left. Deglutition is not affected. Speech and mental state: Only very simple questions are replied to, *i.e.* "how are you," "do you feel well, "does anything hurt you," etc.? Even so, interrogation may need to be repeated several times. The answer when obtained shows H. has heard the question. Nevertheless hearing is poor. Ticking of a watch can be heard when the latter is held close to the left ear; not at all on the right side. Many times the patient merely stares inquiringly when addressed. Repetition of an unanswered question is apt to bring on the characteristic facial spasm. The quality of articulation varies greatly according to conditions. If requested to pronounce monosyllables (*i.e.* concentration of effort upon separate speech elements), it is done with considerable distinctness. But voluntary conversation is at all times tardily attempted and results in language almost or entirely unintelligible. Yet the words he attempts to utter are appropriate to his thought. For instance, he repeated again and again "sick three years" before I could guess what he wished to say. I then asked him to say "three years," which he did, not perfectly, yet sufficiently distinctly to be comprehended at once. Each syllable is enunciated by means of a separate expiratory effort. Often instead of a word an expiratory grunt results. His speech which a year ago was thick, muffled, of nasal quality and monotonous, today shows further loss of modulation and steady progress toward complete loss of capacity to utter articulate sound. H. can read simple script and print, writes simple words upon dictation, and reads what he has written. Errors in spelling tending to phonetization may be made, for instance, knife is written "nife." Spastic movements symbolizing laughter. These are initiated by various sensory impressions. After a few questions are addressed to the patient, particularly some reminding him of his infirmity, or when the inquiring facies show his attempt to comprehend the question and frame a reply, or again, at times if one merely looks at H. intently the ends of the mouth turn upward as in a smile, then as the spasm increases in intensity the month is widened and partly opened, the eyes are narrowed and fill with tears. The face becomes markedly reddened, the wrinkled forehead more deeply furrowed while its engorged veins stand out plainly. During the paroxysm, the drooping left side of the mouth, which ordinarily permits some drooling, is drawn up and widened as on the right side and the relaxed left lower eyelid (Fig. 1) is contracted and raised as its fellow (Figs. 2 and 3). The muscle play of each paroxysm

FIG. 1.

is of ten to fifteen seconds' duration, progresses regularly from slight to intense contraction at the height of the spasm, followed by as gradual a decline. The paroxysm ended, the face loses its congested appearance. Often a single weak, moist cough supervenes. The facies for a few moments is lachrymose and depressed, expressing, it would seem, helplessness to prevent the recurring attack. Instead of this analysis of sequence, one may say that during each spasm the patient acts as one who laughs so hard that he cries. Upper extremities: H. is right handed. He has full use of the right arm; none at all of the left. The latter shows posthemiplegic contraction. Tendon reflexes are increased on the right and greatly exaggerated on the left side. Pin pricks are everywhere felt, but an attempt to take note of sensory discrimination was abandoned. Questions as to touch experienced elicits the usual spasm, but pin pricks alone do so likewise. Thus we note that spastic response may be as readily initiated by general sensory percepts as by those of special sense. Examination of the chest and abdomen is negative. The abdominal skin reflex cannot be elicited. Dribbling of urine is constant and frequent slight incontinence of the bowel occurs. Lower extremities: The legs are noticeably thin. Slight movement in

the left shows partial recovery from complete hemiplegia of that side. The right leg, too, is moved very stiffly. Cremaster reflexes absent; knee jerks are exaggerated, greatly so on the left side. Babinski phenomenon absent on both sides. Slight extension of the proximal phalanx of the left toe, *i.e.* a beginning hammer toe.

Fig. 2.

To summarize, three years after a single apoplectic attack, a patient presents a left hemiplegia, with paresis of the right leg evident as well. In repose and upon volition, the effect of a left hemiplegia is noted in the lower facial muscles. The tongue, lips, soft palate, and vocal cords, too, are paretic. But facial muscles paretic in respect to volitional effort contract normally when symbolizing an emotion, *i.e.*, in movements depicting laughter. Such contraction, however, is purely spasmodic and occurs without appropriate feeling tone.

Disturbances of phonation bulbar in character appearing immediately subsequent to an apoplectic attack make plain their cortical origin, *i.e.* the case is one of pseudobulbar paralysis. Nevertheless, some nuclear degeneration coexists, as is proven by atrophy of the tongue, muscular relaxation and turning out of the lips, absence of the jaw jerk, and more prominent nasolabial fold (overaction of the zygomatici), all on the left side. This is, therefore, a mixed case such as the pathological findings of Oppenheim show are not infrequent. The etiology of pseudobulbar paralysis is now well recognized. Somewhere in their course from cortex to bulbar nuclei the pyramidal fibers are involved practically always through multiple lesions. Thus is explained how various observers, through many years, found typically bulbar symptoms associated with disease now of the cortex, in other cases at varying levels of the subcortical white substance, of the basal ganglia and finally of motor fiber below the latter, yet supranuclear. An interesting chapter of neurology is that which records these initial findings, but it is not my intention to discuss them or the resulting clinical picture in its entirety. My purpose is to call attention to a few facts concerning a single symptom, the type of recurring spasm which the above case presents.

First, a few words as to terminology. Forced laughing and crying or spastic laughing and crying, the terms used by Continental writers to designate the facial spasm under discussion, is obviously a misnomer because both laughing and crying refer to facial movement inspired and accompanied by appropriate emotions. Nevertheless, I have adhered to the usual terminology in the text so as not to lengthen nomenclature already sufficiently unwieldy. In the title of this paper, however, a more correct designation of the facial spasm, as I believe, has been used, *i.e.* facial spastic movements symbolizing laughter.*

Regarding the classification of cases, individual instances have been described as either spastic laughing or spastic crying, or as mixed cases presenting both phenomena. I speak of my case as only symbolizing laughter because at the beginning of the convulsive movement the corners of the mouth turn up (Fig. 2) and because they are likewise seen to be upturned just before the spasm ceases.† At the height of the seizure (Figs. 5 and 6) the mouth continues upturned and yet distress is pictured in the eyes. I believe the appearance of distress is real and inspired by inability to prevent the annoying spasm. But we need remember that expression of the eyes is not discriminating even at the acme of normal facial contraction during the act of laughing or crying. For instance, the twinkle of the eye is an initiatory, emotional movement that accompanies the smile, while on the other hand, tears characterize sadness only when they are associated with the beginnings of muscle play depicting sorrow. Again, were we compelled to rely solely upon oral movements, only the upturning of the corners of the mouth as they initiate a smile or these turning down while the brow contracts in a frown, tell us the nature of the emotive display which the sequent widening of the mouth portrays. Assistance is lent us in interpreting symbolic facial movements, on the one hand, by the character of the emotional appeal to one's self that certain speech or action effects, and on the other, by the audible evidence of mirth or sadness which follows emotive facial movement. Everyone has had experience regarding this, when at some time a chance remark has effected in another facial contraction expressing extreme emotion, the nature of which remains in doubt until respectively audible laughter or sobbing gives the key to the situation. It is because of

*One recalls that normally both laughing and crying may at least in part be spastic, namely, when and to the extent that these, although appropriately initiated, get beyond our control. Another phase in these varying conditions develops when the same "overaction" is obviously due to a pathological condition (Magnus and Romberg's case). In all there is accumulative evidence that in so

Fig. 3.

far as the act of laughing or crying is spastic it is probably subcortical and non-intellectual.

†Fig. 2, which shows the mouth as if smiling, really portrays a seizure in its decline and just before its close. Equally well, however, it depicts the facies as the spasm is being initiated.

these facts that one may desire to learn the criteria upon which classification was made in cases of spastic laughing and crying. Particularly, as regards the mixed cases, in what manner will one recognize both laughing and crying in identical recurring

Fig. 4.

spasms which are neither initiated nor accompanied by appropriate emotion?

Considering its remarkably dramatic character, it is surprising how little the phenomenon in question has interested English-speaking didactic writers. Many textbooks including the last imprint of Osler's "Practice" (eighth edition) do not speak of it. Some writers record as frequent in pseudobulbar paralysis an exceedingly mobile emotional state leading to undue laughter or frequent crying without cause. Lack of emotional control in this as in other cerebral affections is not rare. But mere muscle play, reflex or at most attended with consciousness below the threshold of volition and hence devoid of accompanying appropriate feeling tone is obviously a different matter. It would seem as if this condition might easily be differentiated from excessive emotivity, and, in fact, it has long since in isolated instances been well recognized. The following is a condensed account of a case reported in 1835 by Ulrich and quoted by Romberg[1] under the caption of *risus convulsivus:*

A young man of 24 years had suffered from repeated attacks of erysipelas. Within several years a squint of the left eye, present from childhood, became more marked. His speech "lost its sound;" his gait became stiff. At times he was giddy and obliged to catch at support. After an exposure to great cold, speech and gait suddenly became worse. He now often laughed unintentionally. These laughing seizures never again left him and formed the characteristic feature of the disease. The strabismus increased, the patient seeing double. Progressive paresis of all extremities developed, also spasms in the great toe on stepping or when the extremities were touched. After an attack of tertian ague the patient could walk but a few steps while lending support of his hands. Deglutition and expectoration became difficult. There were several attacks with fever during which occurred spasm of the limbs, retching, and vomiting. The involuntary laughing increased and broke out whenever a movement was arrested. Finally the patient became utterly speechless, but by winking selectively while letters were repeated to him, words were spelled out. The lower jaw hung down and the lips could not be closed, causing great difficulty in administering beverages.*

Ulrich assumed that the medulla was diseased and found upon autopsy areas of softening in it and adjacent parts of the pons. The same involved the pyramids and olivary bodies. Also, there was tumefaction in the shape of "an oblong projection the size of a French bean on the lower surface of the right half of the medulla and a little higher a smaller tumefaction. Several spots of the dura 'strongly reddened' and also the 'remarkably red but not thickened roots' of the 9th, 10th, 11th, and 12th nerves," suggest the process to have been, in part at least, inflammatory. The spinal cord is reported to have been normal. Evidently no examination of the basal ganglia or cerebral tissue above these was made nor are the liver or other abdominal viscera spoken of.

A few other early reports which emphasize association of supranuclear lesions and bulbar symptoms (including emotionalism), with overresponse on the part of muscles of facial expression, merit notation.

Magnus' case chronicled in 1837 was again reported by Romberg,[1] who later attended the same patient. Here the lesion proved to be gyral, two convolutions of the right hemisphere being destroyed by "a hemorrhagic cyst the size of a walnut at the external edge of the right hemisphere of the cerebrum where the anterior lobe adjoins the middle one." It will suffice to say here that this patient presented bulbar symptoms as regards mastication, deglutition, and articulation. Smiling and laughing were normally performed, but as Romberg states, "when she laughed violently she then uttered a peculiar grunting animal sound of which she was in a measure ashamed and which she would have willing suppressed; she therefore tried to shorten it as much as possible; however, the sound continued even after the movements of laughter had ceased and at a time when in a healthy individual no further sound would have been emitted." Even in this case, despite initiation of the laugh by appropriate stimulus, to merely speak of the condition as "emotionalism" is misleading because of abnormal overaction. It is true, sounds of normal laughter cannot be said to be deliberately intentional either, never-

Fig. 5.

*This reference to the lower jaw which eventually could not be closed, together wth the rigid character in general of the paralysis, recalls features of progressive lenticular degeneration[2] whose pathology involves atrophy of the liver and degeneration of the lenticulæ.

theless, in this instance exaggeration of symbolic reflex sounds was pathological. The grunting could not be suppressed as audible laughter usually can. It was therefore due to forced or spastic movement.*

Ross,[4] in his noteworthy essay on labio-glosso-pharyngeal paralysis of cortical origin, *i.e.* pseudobulbar paralysis, does not discuss the disturbances of emotional expression now recognized as exceedingly frequent in this affection. However, he quotes the following circumstances regarding one case (Dr. Croyden's), in which there existed complete facial paralysis subsequent to several hemiplegic attacks involving first the left and then the right side. "When amused the face would be drawn up into an expression of laughter, but never a smile." Clearly this reaction, invariably an over-response in muscles paralyzed to volition, is an example of spastic laughter. We are told that "the tongue was paralyzed, deglutition difficult, power of speech and articulation almost abolished, but the jaws clenched from spasm of the masseters."

This scant recapitulation of a few cases from the literature is pertinent to the fact of subsequent recognition of pseudobulbar paralysis as a clinical entity. In particular, however, it recalls (1) the early recognition that paralysis of bulbar type may be associated with lesions of the corpora striata, and (2) the clinical observation of about the same period, recording the pseudobulbar syndrome associated with unintentional movements of laughter. Clinical and pathological findings of later decades were required to furnish the connecting links, as it were, viz., that forced movements of laughing and crying are a frequent concomitant of pseudobulbar paralysis, and that where these occur frequent lesions of the basal ganglia (most often of the lenticula), or nearby subdivision of the encephalon exist.

Pathology.—This remains an obscure domain. Like the pseudobulbar syndrome in its entirety, the symbolizing movements under discussion occur in association with lesions diversely situated. Nothnagel regarded the optic thalami as the centers for movements of facial expression. Bechterew,[5] too, concludes as a result of experiment and pathological observation that the optic thalami play an important part in the expression of varied perceptions, sensations, and emotional activities. He regards them as motor centers through the intermediation of which the congenital movements of expression, namely, of laughing and crying, are principally executed. These conclusions were voiced more particularly with reference to paralysis of the facial movements expressing emotion when voluntary action of the same muscles was retained. Softening or tumor of the optic thalamus has been found in such cases, but there is not lacking in similar instances other observations wherein this organ remained intact. Lewandowsky[6] goes so far as to say that the idea of a relation between the thalamus lesion and emotion as expressed by the facies may be entirely erroneous. Nevertheless, thalamic lesions again become in evidence in the findings at autopsy of cases which in life had presented forced movements of laughing and crying. But involvement of another basal gray mass, namely, the lenticula, is even more frequently noted. In a few instances subcortical foci of softening within the white matter of the hemispheres and without involvement of the basal ganglia has been exclusively noted.

Costantini[7] tabulated the results of autopsy in respect to localization of diseased areas in forty-nine cases of spastic laughing and crying. These are herewith appended.

Thus we find disease of the thalamus 11 times, of the caudate nucleus 17 times, of the lenticular nucleus 32 times. In a majority of instances more than one of the above were simultaneously involved. If now we note the frequency with which a single basal ganglion with or without other lesion of the encephalon above it, was affected, we find the count as follows: thalamus 1, caudate nucleus 2, lenticula 12. Very frequently (26 times) there occurred lesions of the pons or bulb (or both). This fact is entirely compatible with the theory that the lesion of forced lauging and crying lies at no lower level in the central axis than that of the basal ganglia. In accordance with this idea disease of the pons and medulla would present as its characteristic sign certain neurotrophic effects which mark true bulbar paralysis, but no spastic facial movements. Meantime the frequent association of true and pseudobulbar disease as proven by autopsy, has already been noted. In three cases of the above series (Karplus 2, Ransohoff 1), lesion of the pons alone

*Previous to the Magnus report Richard Bright[3] also had observed several cases presenting the pseudobulbar syndrome. More than this, he not only differentiated such disturbance of articulation from that in a patient presenting real aphasia but also commented upon the relation of all articulatory symptoms to lesions of the subcortical white matter and corpora striata. A condensed history and report of autopsy in a case presenting the commonly observed bilateral apoplectic attacks with articulatory disturbance is as follows: "A lady of fifty years, previously a person of talent, experienced three or four hemiplegic attacks of the left side. Her articulation was much affected. Her spirits were generally downcast, but still she occasionally burst into an hysterical laugh. She was collected but her mind was weak. A later attack deprived her of the use of the right side. She was scarcely able to articulate, but tried apparently to put out her tongue when desired, though she was unable. Sectio cadaveris: eight softened places in the right hemisphere and nearly the same appearance in the medullary portion of the left hemisphere. Some of the little cavities appeared like vesicles in Parmasan cheese; others were simply softened brain. One soft portion was in the posterior part of one of the corpora striata." He writes concerning cases we would classify as motor aphasia: "Sarah Dodds, single woman, aged thirty years, admitted into Guy's Hospital, the subject of hemiplegia of the right side not affecting the muscles of the face. Her articulation was exceedingly imperfect; but the most remarkable circumstance in her condition was the total inability of connecting her words, when she could utter them, with the ideas she wished to express, or the things to which she meant to refer. . . . When asked, for instance the name of her hand, at which I pointed, she said 'a pin,' but immediately signified her knowledge that this was not the right word, though she could not tell what the right word was." Extensive softening and evidence of hemorrhage were found to accord as to probable time of the fatal, as well as of a previous apoplectic stroke. He does not take into account that a brain lesion of one side should affect the opposite one of the body. At the same time he states "the situation of the cerebral lesion . . . occupying chiefly the posterior part of the corpus striatum is further in accordance with an impression I have received from observation and inculcated with regard to lesions which influence the articulation." In another case, in which occurred "a singular incoherence of speech . . . it was manifest that this arose from an inability to collect his words so as to make them representative of his ideas, coupled with some slight difficulty of articulation." A partial recovery occurring, he says "it is not possible to speak positively respecting the exact nature of the cerebral affection in this case, . . . the probability appears to me that the same part of the corpus striatum which has been injured in the last case . . . became the seat of derangement." Thus Bright appears as a very early harbinger of Marie.

is recorded.* Involvement of the anterior segment of the internal capsule occurring twelve times and the posterior segment sixteen times against six times of the knee (the last being so frequently noted in cases of true aphasia), may be significant. But to deduce any conclusion from this would be precarious since recognized nerve bundles change their position as regards the knee at different horizontal planes. *On the other hand, it is remarkable that twenty-seven times in which there occurred involvement of some part of the internal capsule and also disease of one or more of the basal ganglia, the lenticula of the same side (sometimes of both sides) was invariably involved.* In three cases in which a lesion of the internal capsule is reported without involvement of the lenticular nucleus, there is, likewise, no mention made of a lesion in the thalamus or caudate nucleus.

These facts, as well as a study in general of the foregoing tabulation, demonstrate our need to note conditions which relate to subcortical lesions. Here localization refers to nerve tracts, of projection and association, and in case subcortical gray masses be involved, as the added factor, reflex centers inherent to these ganglia. Hence modification of cortical impulses upon basal gray masses may be as effectively brought about by tract interruption or irritation as by lesions of ganglia themselves in which central neurons are rearranged or through which cortical projection fibers pass. *For this reason, for instance, frequency of lenticular disease in the face of evidence that such lesions are vital to forced movements of laughing and crying fails to negative a like effect from softening of supranuclear tracts communicating with this ganglion.* The controversy as to whether cortical fibers reach

*In Ulrich's report, also, only a lesion of the pons was found. However, since the observer's conception of his case was thus verified, it is quite probable that disease within the cerebrum was not looked for.

the lenticula directly or only by way of the optic thalamus may be put to one side.* In any case communication between cortex and optic thalamus and between the latter and the lenticula is known to be extensive, *hence disease affecting this path at a point above or within the thalamus is consistent with the idea that actual motor disturbance emanates only from the lenticula.* I is useless to review the literature in regard to this matter beyond the clinical aspect of cases and the topography of lesions found post mortem because we are bound to end as we begin with theory. The last in respect to the lenticula has long leaned toward a motor function. Mingazzini unequivocally regards this ganglion as a motor organ within which are centers for movements of various parts of the body, including the movements which facially depict emotion. Head and Holmes[9] in their monumental work which enables us to comprehend as never before the characteristic emotive-sensory overresponse associated with disease of the thalamus, have not failed to record occasional associate movements to which class forced movements of laughing and crying also belong. Nevertheless we cannot at present bar the possibility of motor activity emanating from the thalamus itself because, no doubt, all fibers connecting basal ganglia with each other and with the cortex have not been mapped out nor have the functions of known connections been established.* One may

*However, the opinion of Wernicke, which beyond the contention that the lenticula receives no fibers direct from the cortex, regarded this ganglion and the caudate nucleus as independent structures from which fibers originate (*i.e.* gray matter homologous with the cortex), is incompatible with the view that the lenticula is the center for emotive facial movements. This for the reason that identical facial contraction occurs as movements associated with earliest, purely reflex action (*i.e.*, that which effects the initial cry of the new-born babe), merely marking vigorous respiration. It is taught that at this period cortical action is as yet in abeyance. We know that in the beginning this facial contraction occurs with automatic precision and sameness of degree, also that it is enacted in like manner in response to the next stimulus, the sense of physical discomfort induced by hunger. One may assume beginning cortical direction when instead of an invariable cry or crowing laugh, the child facially expresses degrees of emotion by a frown or a slight or broad smile. Tanzi[8] has remarked upon the partial loss of such emotive muscle control at the other extreme of life. He says, "In senile involutions the motor innervation loses its power to express the various shades of emotion by minute and complementary movements (amimia of delicate expressions); but it acquires as if in way of compensation a greater force in the expression of fundamental feelings by means of principal movements (hypermimia of coarse expressions), as Tonnini has observed. This is known to actors, who in playing the parts of old persons, take advantage of it, making themselves what might be termed macromimics."

*Deroubaix,[10] reporting a case of spastic laughing and crying, in which upon necropsy a large area of softening had destroyed the lenticula, anterior limb of the internal capsule, and the white matter of the frontal lobe, all on the right side, interpreted these findings to mean that fibers passing from the cortex through the lenticula to the thalamus were destroyed. He speaks of the faciothalamic bundle. Following Nothnagel, Bechterew, and Brissaud, he believes the thalamus to be the seat of automatic movements of emotive expression, especially of laughing and crying.

say, however, that clinical and pathological observations considerable in number point to abnormal lenticular function as the cause of spastic facial movements devoid of feeling tone or of spastic overaction of normal emotive display. In the last one might see an emotive-motor analogue of super-emotive-sensory perception ascribed by Head and Holmes to abnormal thalamic function.

EARLY RHINOPLASTY.*

By JOHN BETHUNE STEIN,

NEW YORK.

Celsus[1] appears to be the first writer asserting the possibility of transplanting living tissue. He says: "When the loss of substance (curta) of the nose, lips, or ears is not great one can repair it, but if it is great one will produce a more shocking deformity. The operation should not be performed upon aged or sick persons for it may give rise to cancer in those so predisposed." Galen[2] says: "We designate as coloboma the voids existing at the lips, ears and alæ of the nose. These are cured by detaching the skin of the two sides, excising the callosities on their edges, and reuniting them by sutures or sticking plaster." Paul of Ægina[3] (630? A.D.) copied Galen's ideas respecting the restoration of the lost tissue of the ears and mouth, but not that of the nose.

No mention is made of restoring the loss of a nose by any European or Arabian writer since Galen's time until 1295 when Lanfranc of Milan came to Paris. Lanfranc[4] states: "They tell of the nose being completely detached, the patient carrying it in his hand and that after his nose had been fixed on the wound cicatrization occurred; but this is a signal lie because the spirit which presides over life, nutrition, and motion is instantly removed from that part which is separated from the body." He admits, however, the possibility of restoring by bandages or ligatures a nose which is still partly attached to the face. Guy de Chauliac[5] declared himself against "the tricksters who pretended to have restored a nose which was completely severed from the face, because it was often impossible to restore a partly severed one." Peter Ranzano,[6] Bishop of Lucera, recites the following in the Annales Mundi (1442): "At this time there flourished a Sicilian named Branca, the first surgeon of the world, for he had discovered a thing very amazing and unbelievable—the means of repairing the loss of a nose." Branca[7] was credited with being able to restore a lost nose by taking the needed material from either the patient's arm or from the nose of a slave. Branca's son perfected this operation. This new art probably came to Sicily from the East Indies, and not from the Arabs as no mention is made of rhinoplasty in their writings. It is known that the East Indians practised another form of rhinoplasty about this time. Ranzano assures us that this operation by Branca senior was original with the latter. From Sicily the art passed into Calabria, the adjacent Italian province, where it was practised by a family named Vianeo,[8 9] Vioneo, or Bojano. Vincent Vianeo of Maida[10] was probably the first to perform the operation in Italy. After his death his son Peter[11] and nephew Bernardin continued to do it and enjoyed such a reputation at Tropea that their work was designated *Magia Tropæensium*.[12]

Fig. 1—Gaspard Tagliacozzi, 1546-1599, the creator of Autoplasty. From "Les Collections Artistiques de la Faculté de Médecine de Paris.

Alexander Benedetti[13] gives us the first exact information regarding the Vianeo family as follows: "During my time, about the commencement of the sixteenth century, they also learned to correct the deformity of the nose. A flap is detached from the arm and cut in the form of a nose to be applied to the stump of a nose. They detach the skin from the arm with a bistoury, scarify the nose and attach the arm to the head in such a manner that the two wounds are applied one to the other. When union is perfect they cut off, with admirable skill, as much skin of the arm as is necessary to form a new nose. But this artificial nose endures with difficulty a hard winter, and when first put on it is very necessary to guard against having it pulled, because it is liable to be pulled off." Gabriel Fallopius[14] (1523?-1563) and Andreas Vesalius[15] (1514-1564) allude to the Vianeos. They did not think, however, that the flap which was taken from the arm was a simple skinflap but that it in-

*I am indebted to Dr. Noé Legrand, librarian of the University of Paris for the photograph of the statue of Gaspard Tagliacozzi.

cluded some of the fibers of the biceps muscle. Fallopius was of the opinion that it was better to remain mutilated, without a nose, than to submit to an operation which lasted twelve months. According to Jean Baptiste Cortesi,[16] a colleague of Tagliacozzi's who traveled through the Province of Calabria in 1599, all the Vianeos were then dead and even their art of restoring noses was forgotten.

Toward the end of this century rhinoplasty flourished in Bologna, for Gaspard Tagliacozzi[17] [18] (Tagliacotius or Talliacottus) was born here in 1546. He was a pupil of Cardan and received his degree of doctor of philosophy in 1570 and occupied the chair of anatomy and surgery in the University of Bologna for thirty years. Tagliacozzi is regarded as the creator of autoplasty for he was the first to enrich the subject and present it in its ensemble. Little is known of his life. He died at Bologna in 1599 and was buried in the church of Saint John the Baptist in this city.[19] Whether Tagliacozzi devised the operation named after him or obtained the idea from those who practised rhinoplasty before him is not known. In his book, which was published some time after he had performed a number of these operations for restoring the nose, he makes no mention of any one performing this operation before he did. Some of his contemporaries, taking the initiative, wrote upon this subject before the appearance of his book. Paré[20] (1517-1590) tells of an Italian surgeon restoring the nose with remarkable skill; making a pit in the biceps muscle and placing the stump of the nose in it and maintaining the two parts in contact for forty days, adding "but in every case the operation is extremely toilsome for both physician and patient, thereby diminishing its importance." Paré cites also the case of a certain Chevalier de Saint-Thoan who after wearing a silver nose for a long time underwent the operation and obtained thereby a nose of flesh resembling his original one. Paracelsus[21] also treats of rhinoplasty but he could not have alluded to Tagliacozzi as the former died in 1541.

Jerome Mercuriali thought the restored nose was made from the muscle of the arm. This false impression and others of a similar nature were denied by Tagliacozzi in a letter written to Mercuriali[22] in 1586, in which he declared that the stump of the nose was not placed in an incision in the arm, and that he did not use muscle to form a new nose because he could only use the skin of the arm, "in the same way as the gardener uses the bark of a good branch for grafting a tree." Tagliacozzi gives the names of several patients "who were almost more satisfied with their new noses than with those which they carried before."

Tagliacozzi's only work entitled, "De curtorum chirurgia per insitionem, seu de narium et aurium defectu per insitionem arte hactenus ignota sarciendo, etc.," appeared at Venice in 1597 and at Frankfort in 1598. This work became so rare it was reprinted in Berlin in 1831. "He made much noise," says Eloy,[18] "by a work which teaches a method of adjusting a new nose and new ears or lips which were cut out from the flesh. If this physician had not written that he himself had performed this operation one would be tempted to believe it was not so." In the introduction of Tagliacozzi's book, he treats of the importance of the face, particularly the nose, using citations not only from the works of prose writers and poets, but even from the lives of the saints. He gives credit to no one for devising the operation of restoring the nose, although, as we have seen, it was known before his time but says the process of grafting trees inspired the idea and contends there is no part of the body better fitted to replace the lost part than the skin of the arm.

Tagliacozzi concedes the practicability of obtaining the flap for restoring the lost part of the nose from another person, but said this was not always successful, because it was impossible for two persons to be fastened immobile for so long a time. He maintains that his method of operating is free from all danger to a noncachectic patient. He describes what he calls the different degrees of mutilation, and the difficulties of restoring the lost part, saying that they increase in the same proportion. He discusses the preparation of the patient, the instruments, the patients' clothing, his assistants, and the operation itself. In order to render the part from which he obtained his flap more mobile, he pulled upon the skin over the biceps several times with his fingers, then caught the skin between a large flat fenestrated pair of pincers, plunged a bistoury through the fenestra of them and cut the skin through the part exposed by the fenestra. He then passed a bandage through the wound, carefully raised the pincers and daily drew the bandage as a seton through it. When this bridge of tissue became strong and firm enough, through the employment of repercussives, antiphlogistics, astringents, etc., and all symptoms of irritation had subsided, which usually occurred about the fifteenth day, he cut through the upper part of the bridge of tissue. The flap was then turned over and the wound treated. "They say," says Tagliacozzi, "that it is better to detach the flap on three sides, as it saves time for and avoids pain to the patient, but the flap retracts too much and easily becomes gangrenous."

When the flap of skin which Tagliacozzi calls "propago," had cicatrized he proceeded to fasten it to the nose. After the patient's head and beard had been shaved the patient put on a shirt with a hood, the hood fitting his head perfectly. The complicated bandage which was to keep the arm and nose in juxtaposition was also put in position ready to be applied. Tagliacozzi then scarified the stump of the nose with a bistoury and sharp forceps so as to make an even wounded surface. A piece of paper was cut the same size and form as the facial wound, and placed upon the flap, which, after its under surface was scraped, was cut according to the paper pattern. Interrupted sutures of wax-thread were then passed through the flap and the stump of the nose, the arm lifted to the nose and the sutures tied (the sutures being more widely separated from one another on the stump than on the flap). The bandage was then applied and fastened.

When cicatrization had taken place between the flap and stump, which usually occurred about the twentieth day, Tagliacozzi removed the bandage and cap, and while his assistants were holding the patient's arm he cut the flap, at its base, away from the arm. At the same instant the new nose became white and cold, "but," said he, "this phenomenon need not occasion any uneasiness." While his assistants dressed the wound on the arm, hot fomentations followed by a four-tailed bandage were applied to the nose.

On about the fifteenth day, when the nose was firmer, he measured the length of one-third of the

face which is about the average length of the nose and marked with ink its future tip, and the lower borders of the alæ and septum. After cutting out an opening in the flap for the nostrils and making a small flap for the lower end of the septum, tents soaked in white of egg were introduced into the nostrils. Cicatrization of the nostrils usually took place anywhere from the twenty-first to the fortieth day when the operation upon the septum was performed. The stump of the septum and under surface of the flap for the septum were scarified and sewed together with curved needles. The sutures were usually withdrawn on the fourth day.

He placed tubes made of lead, silver, or gold in the nostrils and covered the nose with a cap of the same material, which could be lined with cloth in winter. The tubes and cap were fastened together and the patient was compelled to wear them for two

Fig. 2—A copy of a plate in the work of Gaspard Tagliacozzi ("De Curtorum Chirurgia Per Insitionem. Part II, Page 18) published at Venice in 1597.

years, but sometimes he was permitted to go without them during the day or in hot weather. It was considered very beneficial to expose the nose to the sun's rays which tended to give it a natural color. The application of the bile of a turtle was considered the best means for effacing the cicatrices. "It is possible to restore the lips in the same manner," adds Tagliacozzi, "but the flap of integument for the lower lip should be taken from the forearm and if it is for the ear it should be taken from behind the ear."

Fabricius Aquapendente[23] says the operation is so long, dangerous, and painful that there are few who would submit to it. He states he has had no personal experience with it and that for information those writers should be consulted who have written "ex professo" upon the subject. "I could," says he, "report a great number of observations upon this subject did I not know that the artist himself had written a large work upon it." Jean André de la Croix[24] did not believe in the operation of Tagliacozzi because "the parts are too dissimilar to unite well." Fortunio Liceti[25] thought that Tagliacozzi's operation served to explain the occurrence of double monsters. The celebrated jurist Paul Zachias[26] gave the opinion that if a malefactor was condemned to lose his nose and thereby lost it, it was legal to have it restored by the operation of Tagliacozzi because the operation could be considered a punishment on account of the time required to perform it and the pain it occasioned.

John Baptiste Van Helmont,[27] the Flemish chemist, relates the case of a native of Brussels who had a new nose made by Tagliacozzi at Bologna from the arm of a street porter and that he lost it three months later after his return to Brussels at the instant the street porter died in Bologna. "This example," he says, "proves up to what a distance magnetism and sympathy can act." Samuel Butler[28] (1612-1680) alludes to Tagliacozzi as follows in his Hudibras:

> "So learned Taliacotius, from
> The brawny part of porter's bum,
> Cut supplemental noses, which
> Would last as long as parent breech,
> But when the date of Nock was out
> Off dropt the sympathetic snout."

George Frank von Frankenau,[29] the German scholar and physician, recommended the operation not only for restoring the nose but for other mutilated parts of the body. Nicholas Blegny[30] tells what he considers a doubtful story of a person who, having bought a slave, cut off his nose and had it fastened to another individual. De la Vauguyon[31] thought, as Paré, that it was necessary to force the stump of the nose into an incision made in the arm of the patient, or better a person paid for the purpose, and when union had taken place to cut a sufficient flap of tissue and shape it for the nose. "The ancients," says he, "often made use of their slaves for this purpose." Charles Musitanus[32] was convinced that a nose made from the arm of a patient would adhere firmly to the face. He tells the following: "A gentleman having lost his nose in a duel had a new one made by Tagliacozzi's method but he hesitated to blow it, fearing to tear it off. In order to prove his fear groundless the surgeon seized him by his new nose and pulled him around the house." Carpue[33] says that in an English journal, "The Babillard," (1709-1710) they advise young men to conduct themselves well, because they cannot find a Tagliacozzi on every corner of the street who could restore their noses destroyed by syphilis. W. Rolfinck[34] considers the operation so ordinary that, he says, "When the nose is lost one makes another after the manner of Tagliacozzi."

As time went on Tagliacozzi became more misunderstood and many physicians considered him an impostor. P. Dionis[35] denied that one could make a nose and G. de la Faye[36] reported that he had ineffectually attempted to perform the operation upon animals which had their noses cut off. L. Heister[37] did not believe it possible to restore a nose which had been entirely separated from the body. He doubted the possibility of Tagliacozzi's operation. G. Mauquest de la Motte[38] says: "He must have more faith than reason not to perceive the thing is impossible and the writers who sustain the contrary are liars, as it is not only im-

possible to keep the arm immobile and fixed to the head for the time which is necessary for perfect union, but, as the skin cannot suffice, it is necessary to so injure the muscles that the arm is certainly paralyzed; and finally the new nose is only a foreign body which must sooner or later become gangrenous. Supposing such a piece of flesh could unite, it never can develop nerves or vessels in it and if it is difficult to guarantee a natural nose against the rigors of winter how can one guarantee a false one in which there is no circulation?"

The operation of Tagliacozzi for restoring the nose apparently fell into disrepute and oil-cloth, papier-maché, wooden, and silver noses took its place.

About 1794 Thomas Pennant[39] announced in England that an "artist" of Poonah made a new nose from the skin of the forehead for an Indian who had his nose cut off by the order of the Sultan Tippoo, and that the patient could blow this nose and distinguish odors. Two English surgeons, Thomas Findley and James Cruso,[40] report having seen the operation performed several times at Bombay by a surgeon named Maratte. Carpue says this art existed from ancient times among the Indians where it was transmitted from father to son among certain families or castes.

The so-called Indian method was practised in 1803 in London, without success, by a surgeon named Lucas. Carpue[33] experimented upon cadavers a number of times before performing the operation upon a man (in 1814) who had lost the tip, septum, and cartilages of the nose from a "maladie mercurielle." Before the work of Carpue was known in Germany C. F. Graefe[41] had already performed in Berlin (1816) the operation of Tagliacozzi for restoring the nose, and the following year he performed the Indian operation. At this time Reiner introduced the Indian operation at Munich, having seen the second operation performed by Carpue in England. As the operation of Tagliacozzi was so long and as the Indian operation produced a new scar on the forehead Graefe modified the former and performed it in almost the same manner as Tagliacozzi's operation, which operation then became known as the German operation.

The history of the portrait of Tagliacozzi (Fig. 1) is interesting.[18] A portrait of Ambroise Paré, reputed as having been painted by Pourbus, the elder, was presented the Faculty of Medicine in Paris on February 5, 1852. A medallion in the upper left hand corner read as follows:

Fig. 3.

When in 1903 the portrait was sent to the Louvre to be cleaned and restored evidences of another inscription were seen underneath this medallion. The medallion naming Paré was easily removed and the second medallion (Fig. 4) was revealed. The false superinscription was probably made to obtain a high price for the portrait, which resembled the father of French surgery, Ambroise Paré. But whose portrait was it?

"Coelum non Solum—(Heaven not Earth.)
A.D. 1593, Age 46."

The figures were clues—"A.D. 1593, Age 46." Tagliacozzi was born 1546 or 1547—in 1593 he

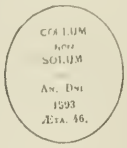

Fig. 4.

would have been 46 or 47 years of age. Another clue was the two pictures in Tagliacozzi's work "De curtorum chirurgia per institionem," 1597, representing patients being treated by the Tagliacozzi method, whose costumes resembled that seen in the portrait. As no picture of Tagliacozzi could be obtained among the prints in the National Library at Paris, a photograph of the portrait was sent to the authorities in Bologna to ascertain if the portrait in question might not be Tagliacozzi's.

The following is the answer to that communication:[18]

"Bologna,
"September 21, 1909.

"The photograph of the portrait you sent me is

Fig. 5—Statue of Gaspard Tagliacozzi in the theater of the Anatomical Institute at Bologna. "And in order to make his work known to posterity they put a nose in his hand." (Eloy.)

surely that of Gaspard Tagliacozzi, the celebrated anatomist of Bologna, to whom is dedicated an inscription in marble and a statue, by A. Levanti, which stands in the Theater of the Anatomical In-

stitute. I enclose a photograph of the statue. Both photographs correspond perfectly.

"ALBANO SORBELLI,
"Librarian,
"(Library of Bologna.)"

The statue "resembles him," says Eloy, "and in order to make his work known to posterity they put a nose in his hand." Sorbelli[18] wrote in a later letter, October 16, 1909, that, "having succeeded in restoring the nose, ears, and other parts of the head, the most noble part of man, Tagliacozzi was considered a new creator, almost a God, and Mutio says of him: "'*In utraque mendenti arte, pene divinus.*'" This "Almost Divine" explains the "Cœlum non Solum" discovered on the portrait.

MILD MANIFESTATIONS OF SYRINGOMYELIA,

WITH REPORT OF THREE CASES.

BY C. BURNS CRAIG, A.B., M.D.,
NEW YORK,
CHIEF OF CLINIC, FIRST DIVISION OF THE NEUROLOGICAL INSTITUTE.

THE increasing number of reported cases of syringomyelia appearing in American literature bears noteworthy testimony to the more widely spread knowledge possessed by the general practitioner and to his greater care in examining cases.

FIG. 1—Case I. Note the atrophy of the forearm and the flattening of the palmar eminences. The symmetry of the shoulder is preserved.

Syringomyelia gradually evolved into a clinical entity between the years 1882 and 1888, due to the correlation of a symptom complex with the morbid anatomy by Schultz of Dorpatt, and Kahler of Prague. Practically unknown in this country 20 years ago, and only rarely detected 15 years ago, commonly classified as a disease of the motor system, confused with amyotropic lateral sclerosis and chronic myelitis of all varieties, it has now come to fill many pages of medical literature and typical cases are readily recognized by the practising physician. There are, however, a group of cases, mild or incipient they may be called, whose real status passes unrecognized until they drift into the neurologist's clinic. From such cases a careful elicitation of the history alone serves to arouse suspicion as to the nature of the affection, *e.g.* a stiffness, numbness, and loss of dexterity in the fingers, grad-

nally increasing in severity, usually without pain, associated at one time or another with an accidental painless burn; a slowly healing and painless traumatic ulcer on the hand; a visual sense of injury to the hand, rather than a pain-perceptive

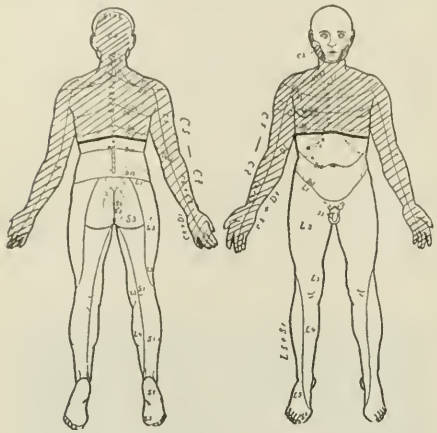

Fig. 2.—Case I. Area over which heat and cold are not distinguishable and a sharp pinprick is not painful.

sense makes it possible to hazard the diagnosis. The suspicion is readily confirmed by physical examination. The following cases serve to illustrate this type:

Case I.—Mr. J. B., aged 21, was graduated from one of the leading technical colleges in the country one year ago, as a mechanical engineer. He had always enjoyed the best of health and had taken an active part in athletics. Family history negative. He appeared in Dr. Joseph Collins' clinic on June 13, 1913, complaining of numbness and slight clumsiness in the fingers of the left hand and his attention had been called to a diminution in the size of the left arm. There was never any pain. He had passed through the hands of numerous physicians and had as many diagnoses, *e.g.* "atrophy," "progressive paralysis," and by one physician the cervical vertebra was radiographed. The patient was an expert violinist and he first noticed about a year ago that the fingers of the left hand were not entirely obedient in fingering the strings. He would blow upon his fingers or slap them upon his knee "to get better circulation." He found that he could no longer hold a cigar between the index finger and thumb of the left hand, with ease; that when he did, he would often drop the cigar or jab it into his lip instead of his mouth. He further discovered, being athletically inclined, that when inserting the left hand into a baseball glove the fingers fumbled clumsily about when getting into the glove fingers. During the past winter the lack of skill in fingering the strings of the violin gradually became more marked, so that by February, 1913, he was compelled to put the fiddle on the shelf for good. On a cold day especially "the hand would feel numb" and the fingers would be inaccurate in performing finer movements. There has never been any appreciable loss of strength in the arm, but this spring (1913) an impairment in static control was manifest in finishing a swing with a baseball bat; the left hand upon which the chief stress comes at the end of the swing would frequently "forget" and let the bat slip away, unless he particularly put his mind on holding it. The same was true of carrying a suitcase, the hand would suddenly let go. He did notice, however, that in washing his head or in carrying a towel to the opposite side of the chest, he could bring very little pressure to bear with the left hand. In drafting he finds difficulty in holding down the T-square and triangles exactly with the left hand. He has never experienced any difficulty in the use of the right hand or arm.

Physically, the patient is a well-developed young man of excellent physique. His sole defect is confined to the left upper extremity. The arm and forearm show a degree of diminution in volume which is just appreciable, and there is mild atrophy of the intrinsic muscles of the hand, chiefly the thenar eminence, and to a less degree the hypothenar muscles. The left arm is slightly ataxic, but adiadokinesis is not present. The gross power of the flexors and extensors, supinators and pronators of the forearm, and the hand grasp are diminished. The contour

Fig. 3.—Case II. Note the straightened border of the left hypothenar eminence and the redundant skin and flattening of the thenar eminence, due to mild atrophy.

of the shoulders is preserved; the lower extremities are normal; the face is uninvolved; in fact, the physical examination is otherwise negative except for the most sur-

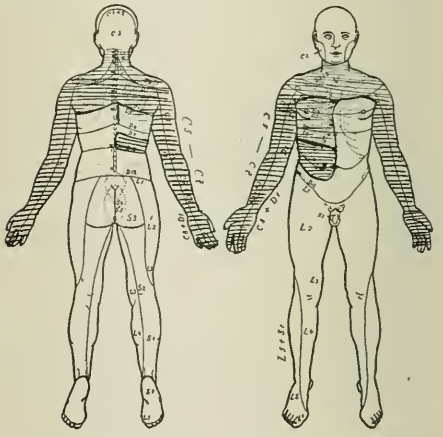

Fig. 4.—Case II. Area of dissociation of heat and cold and diminished pain sense.

prising and most important discovery that he is completely anesthetic to temperature and to pain from the crown of his head to the tenth dorsal vertebra, and from his chin to the seventh rib, quite symmetrically and including both arms. The lesion is thus placed high in the cervical cord, the gliosis encroaching upon the indicated

sensory tracts of the cord from the first cervical to the seventh dorsal segment (see chart). The cerebrospinal fluid was entirely negative.

Case II.—July 6, 1913. Mr. W. W., aged 28, a clerk, of Swedish descent. His present complaint is a flattening of the hand at the base of the left thumb. He is not conscious

Fig. 5.—Case III. Note the kyphosis and slight flattening of both shoulders. The patient is unable to hold the thumb in the abducted position. Note also the wasting of the thenar eminence.

of any loss of power and has no pain. On July 13, 1910, having been previously entirely well, the patient went for a swim in the ocean. On entering the water he noticed with some alarm, having been an expert swimmer, that he could not strike out with strong strokes of his arms. After several trials he gave it up and left the water and went home. The evening of the same day patient lay down on the bed and fell into a light sleep, from which he was awakened by severe pains over the precordial region. He got out of bed, but fell, owing to the weakness of the left leg. He then discovered that he was unable to raise left arm. There was no numbness nor pain in the extremities at that time. The next day he had an occasional shooting pain down the left arm, and two days later there developed inflammation of the left eye and a purulent watery discharge from the left ear, although there had been no previous pain in the ear. A buzzing sensation began in the head and there was also, as he thought, "a buzzing sound" in the left arm. This he thought audible to other people. The left arm and leg gradually became stronger. About two weeks later it was noticed that there was some flattening of the muscles at the base of the thumb. The flattening increased until it was quite marked, at the same time his strength returned, as he thought, completely, and although left handed he noticed no impairment in the use or power of the left arm or hand. One very peculiar symptom has remained as a vestige of his original attack, namely: when he falls into light sleep in a sitting posture, and occasionally when in bed, he is usually awakened by palpitation of his heart, which subsides immediately when he stirs about.

On inspection he presents a picture almost identical with the previous case. There is no shoulder atrophy; the atrophy of the arm and forearm is less, but that of the muscles of the hand, especially of thenar eminence, is more marked. The supinators and pronators of the left forearm are slightly weakened; hands grasp by manometer, left 90, right 100. The tendon reflexes at the knees and ankles are a trifle plus. The skin reflexes of the upper and lower abdomen and right cremaster are absent. No Babinski. There is no scoliosis. Heart and other viscera normal. Wassermann reaction negative. The sensory examination reveals perfect tactile sensibility, but an absence of pain and temperature sense from the occiput to the scapular spine on the left and to the twelfth dorsal vertebra on the right; anteriorly from the chin to the third rib on the left and to below the umbilicus on the right. There is a band on the right where the anesthesia is not complete (see chart). This finding likewise places the lesion high in the cervical cord and the cardiac symptom is probably due to extension of the gliosis into the region of the vagus nucleus.

This case is especially interesting because of the violent precipitation of the initial symptoms and the possibility of its being of infectious origin from a purulent otitis, though it is probable that this was a coincidence and that a syringal hemorrhage, as described by Gowers, had occurred.

Case III.—July 18, 1913. K. N., aged 39, a book-binder. His previous history is negative, except for typhoid fever at 18 years. Venereal disease denied. He began to notice a feeling of numbness in the little finger of his right hand about ten years ago. Some two years later he was conscious of a similar numbness, as though he "had been lying on it," in the entire right arm, right side of the trunk, and even extending into the right lower extremity. This sensation became constant and still remains, but has at no time interfered with work. Five years ago the right little finger began to curl in and he could not straighten it. Some months later the ring finger did the same thing. Since then there has been gradual loss of strength in the right arm, and an inability to detect injury, *i.e.* a cut or burn, on the right hand. Originally a right-handed individual, he now finds it easier to use his left hand in performing finer movements.

Physically, he is a short, thick set German-Jew with a mild scoliosis and rounded kyphosis of the upper thoracic spine. The contour of both shoulders has been flattened by deltoid atrophy. Atrophy of the right forearm is apparent, but is more marked in the hand where thenar and hypothenar eminences and the interossei are considerably wasted (see photograph). There is a corresponding loss of power in the hand, right 70, left 100, and abduction of the fingers is impossible; when forcibly spread abduction is extremely weak. The flexors of the wrist are of fair strength, but extension is very weak. There is no trophic change in the nails, although the hand shows evidence of frequent injury. Coordination of the arms is not impaired. The left hand, although not very strong, shows no atrophy, nor do the feet show any change. The sensory examination again discloses the real nature of the disease, as there is an anesthesia to hot and cold and pin prick from the occiput to points just below the scapular spines and from chin to the second intercostal space on the trunk. On the right arm anesthesia prevails throughout,

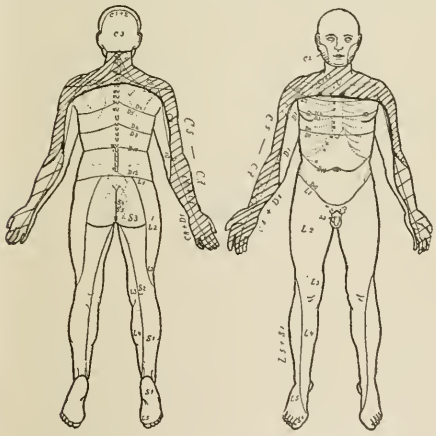

Fig. 6.—Case III. Area of pain and temperature anesthesia is heavily shaded; area of hypesthesia is more lightly shaded.

except over the inner surface from the elbow up where sensation is normal; on the left arm anesthesia extends down the outer border to the elbow. Distal to this there is hypesthesia. The ulnar border of hand and arm preserve normal sensation (see chart). Wassermann negative. The lesion in this case is likewise in the cervical

cord, extending from the third to the eighth cervical segment.

These cases show a great disparity between the motor inconvenience experienced by the patient and the unsuspected sensory disturbance. The mild degree of atrophy and other trophic disturbance and the comparatively slight loss of motor power indicates the remarkable manner in which the depredation of the spinal gliosis is confined in the early stages, at least, to the sensory tracts bearing thermic and pain sensations, tactile and postural sense being unimpaired. The symmetry of the sensory disturbance is worthy of notice favoring the belief that the anlage of the disease is of congenital origin consisting of an inclusion of glial cells in the posterior median fissure of the spinal cord during the involution of the neural ectoderm. The value of careful sensory examination in cases of slight motor disturbance and even before this stage, in the period of paresthesia, perhaps, need not be dwelt upon, except to point out that such cases as those described above wander from one physician to another until someone manifests sufficient interest to devote the short time necessary to make a few sensory tests, then the true nature of the disease is disclosd.

THE ROENTGEN RAYS IN THE DIAGNOSIS OF DISEASES OF THE STOMACH.

By I. H. LEVY, M.D.,

SYRACUSE, N. Y.

ASSOCIATE PROFESSOR OF CLINICAL MEDICINE, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY, PHYSICIAN TO THE HOSPITAL OF GOOD SHEPHERD, SYRACUSE

Since the introduction of the Roentgen rays in medicine, they are proving not only of great use to the surgeon, but also to the internist, and even to the physiologist and pharmacologist. The internist they have furnished with another pair of eyes, enabling him to peer into the recesses of the body and spy out some of its secret workings. They enable him to see the diaphragm move with respiration, to see the heart beat, following the pulsation from the sinus down the auricle to the ventricle. He can see the bismuth meal starting at the mouth pass down the esophagus into the stomach. He can see it forced through the pylorus into the duodenum, rush rapidly through the small intestine into the cecum, and then trace it from there to the rectum. The Roentgen rays give us a definite idea of the shape, location, and size of the stomach. They tell us of the depth, rapidity, and direction of the peristaltic waves. They enable us to determine the motor power of the stomach, and also by the aid of variously coated bismuth capsules of different weight, the amount and character of the secretions. Any one diagnostic aid that can tell us all these things cannot but be of great aid to the physician.

But it cannot be too strongly emphasized that the *x*-rays are not to be invoked as a first aid. Alone they do not make the diagnosis. They are simply a diagnostic aid, and should only be employed in conjunction with all other aids. A history must be taken and a careful examination, both physical and laboratory, must first be made, and then only should a Roentgen examination be undertaken to supplement or complete the previous examination. The Roentgen rays, whether we use the fluoroscope or radiograph, give us only a picture, and it is its interpretation that is all important. The *x*-ray examination must be checked up and controlled by all other methods, and if it contradicts the other findings, great care must be used in coming to a conclusion. In gastrointestinal work we make use of both the fluoroscope and the radiograph. Both are important and necessary, but between the two, the screen work is by far the more valuable. The radiograph gives us a picture of the stomach at a given moment. As the stomach constantly changes, owing to the peristalsis, the information so obtained is limited. Lately the cinematograph has been used to remedy this deficiency. But even this only partially overcomes it, besides the larger number of plates necessary makes it time consuming and expensive. The fluoroscope, on the other hand, enables us to observe the stomach for five, ten or even fifteen minutes continuously. The peristaltic waves can be studied, whether the indentations are of shallow, normal, or abnormal depth; whether the rate is normal, and whether antiperistalsis is present. The food can be seen passing into the duodenum. We can see whether there is an incontinence of the pylorus; also whether the food passes in slowly or in jerks or squirts. It enables us to determine whether the stomach is movable or adherent to the neighboring organs. Also in the study of hourglass stomach, we must often decide between a true and pseudo-hourglass contraction. In the former case forcing the food upward with the hand back of the screen, we can see whether the contraction is permanent or disappears. The picture or radiograph is important as a matter of record, and also because it enables us to study the plate at our leisure, and, occasionally, small details, which are not brought out on the fluoroscope, can be observed.

In the chest, owing to the contrast in density between the heart and lungs, we can examine the patient without any preparation. In abdominal work, owing to the density of the organs being nearly alike, in order to get a contrast some metallic salt must be used. Bismuth subcarbonate or barium sulphate is usually employed. The patient is given the bismuth meal and examined immediately after or six hours later. In the former case the patient must be seen at the end of six hours to determine whether the stomach has emptied itself. When the patient is first examined six hours after taking his meal, a second bismuth meal may be necessary, if the first has already left the stomach, to determine its location, shape, and peristalsis. This latter method was introduced by Haudek. My preference is for the one meal and two examinations. Two bismuth meals six hours apart are not always agreeable to the patient. The large amount of bismuth ingested, equaling three ounces or more, is, however, free from danger. As said before, by this means we are enabled to determine the shape, size, and location of the normal stomach. The Luschka form, as pictured in the anatomies, that is, a stomach placed nearly horizontally, the pyloric outlet nearly on a level with the cardiac orifice, does not exist. Two forms have been described, one by Rieder, the other by Holzknecht. The former has shown that the stomach is shaped like a fishhook or letter J. The axis of the stomach is nearly vertical, the pylorus is placed considerably above the lower pole. He found this type in about 80 per cent. of normal cases. Holzknecht, on the other hand, has described the cow horn form as the normal. It differs from the Rieder form in that, instead of being vertical, its axis is about 45° and the pylorus

is near its lowest point, there being no "Hubhöhe" or short arm of the letter J. This type is found in about 20 per cent. of adults. But despite this, Holzknecht believes this to be the normal type. He ascribes the presence of the Rieder form in 80 per cent. to pathological changes. Holzknecht argues that the cow horn form is best suited for rapid emptying. This is true, replies Rieder, but for digestion, the letter J stomach is more suitable, as it allows the food to remain in the pars pylorica longer, becoming more intimately mixed with the gastric juice, and better ground up before passing into the intestine. The large majority are with Rieder on this question.

The *x*-rays have also taught us that normally the empty stomach is in a state of collapse, *i.e.* the walls are in apposition, it is only when food enters it that a cavity becomes visible. If we watch the entrance of a mixture of bismuth and water into the stomach, we at first observe a narrow streak along its left wall, which reaches to its lowest part, if more be swallowed the streak becomes wider and wider, but there is very little descent of the lower pole. The walls of the stomach firmly hug the food, the upper part of the fundus remains clear, and that is filled with gas. This "Magenblase" or stomach bubble is always present when there is food in the stomach. It is the tonus or contraction of the stomach musculature that causes its walls to firmly grasp the food within it. In a widely dilated stomach the food at once falls to the bottom. As more food is swallowed, the lower pole of the stomach stretches and sinks. No matter how great the meal, such a stomach wall never squeezes its contents.

The Roentgen picture of the stomach changes somewhat with the change in position. Both the fluoroscope and radiographic work is mostly done in the standing position, and the above forms refer to this position. In the reclining position, the stomach appears more horizontal. Respiration, drawing in the abdominal walls, as well as pressure of the organs within the abdomen, may change the form and location of the stomach.

The Roentgen rays also permit us to judge of the motor function of the stomach. We observe its peristaltic movements, also the length of time the food remains in it. The peristaltic waves begin immediately after the ingestion of the food. They begin about the middle of the organ and move towards the pylorus. The waves are of varying depth at the antrum pylori, they are so deep as to completely obliterate the cavity. Their function is, no doubt, to bring about a better mixture of the food in the pyloric area. The emptying time of the stomach is determined by observing it at varying intervals after the ingestion of the bismuth meal. Rieder and Jolasse place the normal at three hours, Kastle two to three and one-half, Holzknecht and Haudek between two and six hours. All are agreed that food remaining in the stomach longer than six hours is pathological.

The Roentgen rays give us an easy way of determining a gastroptosis. The picture is characteristic. While the normal stomach does not reach much below the navel, the ptosed stomach reaches far below. The stomach itself is long and narrow, its axis practically vertical. There is, however, no disturbance of the muscular tonus in an uncomplicated gastroptosis. There being no increase in size, the Rieder meal fills the entire stomach. The stomach is rarely the only organ involved. Usually the kidney, colon and other organs are also lower in the abdomen than normally. Enteroptosis is not as a rule due to faulty dress or pregnancy. It is very common in the male, and is frequently encountered in young children. In ninety per cent. of the cases it is due to what Stiller calls "Asthenia Universalis." In other words, it is usually a constitutional condition. In this type I am inclined to believe with Boninger that it is due to an abnormally long development of the body—the steeple style of architecture, as I am inclined to call it. The stomach is long and narrow, but not out of proportion to the rest of the body.

As was said before, the normal stomach wall closely grasps its contents. When the muscular tonus is lost or diminished, we have atony of the stomach. Atony, however, does not mean disturbance of the motor function, as the atonic stomach may empty itself within the normal limits; while on the other hand, food stagnation may occur when there is even muscular hypertrophy, as in the early stage of pyloric obstruction, either organic or reflex. Frequently the two go together. An atonic stomach is characterized in the Roentgen picture by its length, but differing from the ptosed stomach by also being broader than normal. The cavity of the stomach, in other words, is larger, and, consequently, the same amount of food does not fill it. The food at once drops to the lower pole. No matter how large the meal, the lower portion of the stomach is the only part filled. The atonic stomach is usually ptosed also, the lower border, the lesser curvature and the pylorus all being lower than the normal. The ptosed stomach may be atonic, the latter when present being secondary. The distinction between the two conditions is, the ptosed stomach is simply longer, but not larger than normal, the walls grasping the food; the atonic stomach, on the other hand, is larger, the muscular walls do not firmly hug the stomach contents, there is a loss of what Stiller calls the peristolic function. Clinically, the diagnosis of atony or dilated stomach is frequently made from the presence of succussion or splashing sounds obtained on tapping the abdomen. The succussion sounds are always obtained when a large area of stomach is close to the abdominal wall. In ptosis without atony, succussion sounds are obtained. It is a question whether a dilated stomach is ever due to muscular weakness. It is usually synonomous with pyloric obstruction, either organic or reflex. The sign of a dilated stomach is stagnation of food.

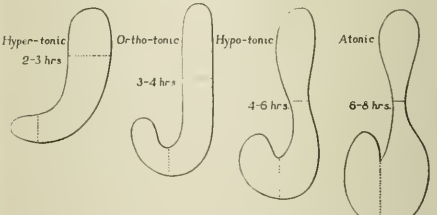
Does the *x*-ray help us in the diagnosis of ulcer of the stomach? In 1906, Hemmeter reported three cases in which he made the diagnosis of ulcer of the stomach by means of the *x*-rays. He interpreted the dark spots within the stomach shadow due to bismuth adhering to the base of the ulcer. The belief today, however, is that in simple ulcer the bismuth does not help us to locate the lesion. In fact, Haudek and Clairmont excised bits of the mucus membrane from the stomach of dogs, and sewed lead markers in these areas, and in no case did the bismuth deposit coincide with the markers. But even though the Roentgen rays do not alone diagnose the ulcer, they can, however, be of great use in reaching a diagnosis, as we know in a large number of cases of ulcer of the stomach, there is a sensitive spot in the epigastric area. But this is not a pathognomonic sign, and ordinarily we are not able to say if the painful spot corresponds with the location of the ulcer. When we have the patient before us, and the stomach shadow on the fluoroscope and then

test for the painful spot, we can at a glance tell whether it falls within this shadow or not. We can even go further and note whether this spot moves with the stomach, when we tell the patient to draw in the abdomen. If the spot moves with the changed position of the stomach, it must of necessity be connected with it. Thus, it can readily be seen that the determination of such a painful spot is of much more diagnostic value than simply a sensitive spot on the abdomen. Then it has been observed and verified by operation that in ulcer of the stomach there may be reflex disturbance of the shape of the stomach at a point distant from the ulcer. For example, in ulcer of the lesser curvature, frequently on the greater curvature there is a decided drawing in of the stomach wall, making an hourglass stomach. While this is not a constant find, yet its presence makes the diagnosis of ulcer of the lesser curvature almost a certainty. These ulcers, especially when of long standing and contracting, lead to a characteristic formation. The pylorus is found higher than normal and far to the left, giving the stomach the so-called snail or "Schneckenform." By far the most common Roentgen symptom of ulcer, no matter in which part of the stomach located, is a disturbance of the motor function. Even when the ulcer is far from the pylorus, there is at times a reflex spasm of this part, and consequently stagnation of food. Six hours after a test meal a fair portion of the food can still be found in the stomach. Haudek says that he has never failed to observe this with ulcer. Personally, I cannot agree with him. I have seen cases of undoubted ulcer proved at the operating table, where there was no six hours' rest. Faulhaber is also of this opinion. In cases of chronic ulcer at the pylorus leading to stenosis, the diagnosis by means of the *x*-rays is very simple. The stomach under these circumstances is immensely dilated. The bismuth meal at once drops to the bottom of the stomach as if it fell into a bag. Six hours later examination shows a characteristic rest. It is half-moon shaped and extends considerably to the right. There is another form of ulcer of the stomach in which the *x*-ray makes a positive diagnosis. In fact, this is the only means of making a diagnosis previous to the operation. I refer to the "ulcus penetrans callosum" of Haudek. We sometimes encounter a callous ulcer in the stomach. The walls about the ulcer become indurated and thick. There is an obliterating endarteritis. The stomach grows adherent to the surrounding organs like the liver or pancreas. The ulcer extends crater-like into these organs, forming what Haudek calls a "Nische" or diverticulum. The bismuth finds its way into this pocket, and remains there for some time, and, consequently, both on the screen and plate, we find a dark area surmounted by a clear space above, which is filled with gas. These ulcers are usually located on the lesser curvature, and invariably there is a painful spot directly over it. A picture of this kind once seen is so characteristic that it can never be forgotten.

We have still another type of stomach that can be diagnosed with certainty only by means of the *x*-rays. Formerly the diagnosis was only rarely made. Now it is a very simple matter. I refer to the hourglass stomach. This results usually from ulcer or cancer. An hourglass stomach is one that has two pouches connected by a narrow channel. An *x*-ray picture of the condition is very convincing. The surgeon often sees these cases on the operating table, but does not recognize them, for at this time the stomach is empty and collapsed. To make the diagnosis, the food must be seen first in the upper pouch, and then in the lower. So the surgeon is in no position to contradict the Roentgen diagnosis of hourglass stomach.

The stomach, as the result of perigastritis or adhesions, may be adherent to the surrounding organs or structures. The adhesions cannot be seen with the *x*-rays, yet we are able by this means to suspect their presence. If the stomach be drawn to one side, and while making a fluoroscopic examination, we try with the hand to separate and push it in its normal position, and are unable to do so, or if we tell the patient to breathe deeply or draw in the abdomen, and the stomach remains fixed, we can again suspect adhesions. But this is a diagnosis that must not be made hastily by the roentgenologist. He must not diagnose more than he sees, for by so doing he brings discredit on this means of diagnosis. Better diagnose too little than too much. Haudek advises the greatest caution, and himself rarely makes a diagnosis of adhesions.

And now we come to a very important chapter of this subject, namely, the diagnosis of cancer by means of the *x*-rays. Can the *x*-ray diagnose cancer in the early stages? I am sorry to say that in its incipiency it cannot, nor can any other means. We are greatly in need of a method to detect this dread condition in its very earliest stages. The number of means proposed is an indication of this lack. But as a matter of fact, even though we had such a sure means, the onset of cancer is often so insidious, and its progress so gradual, that when the patient presents himself to the physician, the disease has progressed so far that the diagnosis is very simple by the ordinary means at our disposal. In these cases, when the diagnosis is made, there is nothing more to be done, as the time has already gone by when even surgery is able to offer any hope of cure. Cancer of the stomach is so common and its outlook so hopeless that any means which may aid its earlier detection should be taken advantage of. What can the *x*-rays do to help us? When a tumor is present, which encroaches on the lumen of the stomach, by means of the Roentgen rays we can see the defective shadow. There is an absence of the bismuth shadow, corresponding to the location of the growth. This can often be discerned before the mass is palpable. This already is a great gain. But we can often suspect cancer even before there is a break in the bismuth shadow.



Types of stomachs and their emptying times. (Schematic, after Schlesinger.)

There should be a definite relation between the shape, peristaltic wave, and the motor function of the stomach. Schlesinger has divided stomachs into four types, according to the rapidity with which they empty themselves. These he calls hypertonic, orthotonic, hypotonic and atonic. The hypertonic,

or Holzknecht's cow horn type, should normally be empty at the end of three hours; the orthotonic, or the Rieder type, at the end of four; the hypotonic at the end of six; the atonic at the end of eight. Consequently, a hypertonic stomach with a six hours' rest would be pathological, while the same sized rest in an atonic-shaped stomach would not permit the same conclusion. Likewise a stomach showing normal or increased peristalsis and a six hours' rest would lead to different diagnosis than the same shaped stomach with shallow peristaltic waves. But the *x*-ray tells us more than that a growth is present. It tells us something of the nature of the growth, whether a scirrhus, medullary or contracting carcinoma is present. It also gives the surgeon valuable information in regard to the possibility of removal of the growth, its size, relation to the surrounding structures, and frequently saves the patient an operation. In other words, the Roentgen picture takes the place of an exploratory operation. Although in the diagnosis of cancer unfortunately, as yet, the Roentgen rays do not make the early diagnosis possible, yet I believe it may safely be asserted that, if all cases were seen early enough and *x*-rayed, the prognosis of the surgical treatment of gastric cancer would be much better.

In conclusion, I can but reiterate that the *x*-ray is not a nickel-in-the-slot machine, where the patient comes out with the diagnosis attached. The interpretation is all important. In all cases it is wise to be conservative, not to diagnose too much, and above all not to neglect every other diagnostic method that may be of aid. Only by careful comparison and checking will grave errors be avoided.

717 East Genesee Street.

THE FREQUENCY OF AMENTIA AS RELATED TO SEX.*

By LETA STETTER HOLLINGWORTH, M.A.,

THE CLEARING HOUSE FOR MENTAL DEFECTIVES, NEW YORK CITY.

The statistics of various institutions for the feeble-minded have repeatedly shown that there is a preponderance of males among inmates. This has led to the statement by general writers, and also by men of science, that there are more mentally defective (idiotic, imbecile, and feeble-minded) individuals among males than among females. Careful reflection on our present social organization, however, suggests to the student of social questions the fallacy in this conclusion. Observation of patients as they are brought to the clearing house for mental defectives strengthens this suggestion. The question arises as to whether the social conditions which lead defectives to the clearing house, and hence to institutions, apply equally to both sexes; and whether statistics of institutions have any validity as an index of the real frequency of amentia as related to sex.

Havelock Ellis,[1] in a chapter on "The Variational Tendency of Men," makes this comment: "Idiocy is almost everywhere recognized as more common in males than in females." E. L. Thorndike[2] says: "Greater male variability should result also in a great preponderance of men amongst the most idiotic idiots. Just this seems to be the case." The Royal Commission of Great Britain of 1904 realized the fallacies involved when conclusions are drawn from institutional statistics and sought to ascertain more exactly the facts with regard to the incidence of amentia in the population. Tredgold[3] gives a table based on the report of the Royal Commission and remarks upon it as follows:

"SEX OF 12,120 AMENTS: ROYAL COMMISSION, 1904

	Idiots	Imbeciles	Feeble-minded		Totals
			Children	Adults	
Males.....	303	959	3244	2179	6685
Females...	282	848	2193	2112	5435

"It is thus seen that, considered either in regard to each degree or collectively, there is a slight preponderance of the male sex, the relative proportion of males to females being practically 6 to 5."

These data are, of course, much more reliable than those upon which previous conclusions had been based, but the Royal Commission was not especially interested in the frequency of amentia as related to sex, and its members do not seem to have considered the fact that their procedure was scarcely designed to apprehend as many females as males, though much more thorough in this respect than previous methods. In the first place it is obvious that the definition of *feeble-minded person* which they adopted, "One who is capable of making a living under favorable circumstances, but is incapable from mental defect existing from birth or from an early age (*a*) of competing on equal terms with his normal fellows, or (*b*) of managing himself and his affairs with ordinary prudence," applies unequally to males and females. Females belong to a non-competitive and dependent class and are not so readily recognized as defective since they do not have to compete mentally to maintain themselves in the social milieu. A second source of error lies in the fact that the Royal Commission did not, so far as stated,[4] investigate the mental status of professional prostitutes. There is little doubt that a very considerable number of imbecile and feeble-minded females would have been discovered in this class. Indeed, precise data are already available on this point. Goddard[5] having published in 1911 a study of 56 wayward girls, 52 of whom were found to be feeble-minded according to the Binet measuring scale.

It is notable that in the table reproduced from Tredgold the preponderance of males increases as the degree of defect decreases. Among the lowest idiots the ratio of male to female frequency is 1.07; among imbeciles it is 1.13; among feeble-minded children it is 1.47. This suggests that the females slip through detection into an ever higher and higher classification. Tredgold adds: "It is probable that of all aments born a considerably greater preponderance than this are of the male sex; but that the number of these is subsequently diminished by a relatively higher infantile mortality." He does not tell us, however, whether he ascribes the greater preponderance of defective male infants to a greater relative frequency of amentia among males, or to the fact that the birth rate for males in general is higher than for females.

Goddard[6] tested by the Binet measuring scale 1,547 school children, this number comprising one whole school system, and he gives the distribution of mental status for girls and boys separately, thus:

*I am indebted to Dr. Max G. Schlapp, director of the Clearing House for Mentral Defectives at the Post-Graduate Hospital, in New York City, for permission to study and to cite these data.

TOTAL BOYS AND GIRLS

	4 7 Yrs. Be low	3 Yrs Be low	2 Yrs. Be low	1 Yr Be low	At Age	1 Yr Abv	2 Yrs. Abv	3 Yrs. Abv	4 Yrs. Abv	Tot al
Boys..	31	36	87	192	290	168	24	7	0	835
Girls	22	43	68	121	261	163	25	7	2	712

Goddard remarks upon this table as follows: "It will be seen by looking at the figures for the boys and girls * * * that there are more backward boys than girls. This is a very neat confirmation of the tests, since it agrees with statistics everywhere that there are more defective boys than girls. There are more in institutions for the feeble-minded, and although this is usually accounted for by the explanation that girls are more easily taken care of at home, therefore do not get into institutions, yet in view of the facts, there is no doubt that there are more feeble-minded boys than girls. There are more boys in the special classes in London and in the *Hilfsschulen* in Germany, and in the special classes so far formed in the United States, and everything agrees with this."

Goddard tested a total of 835 boys and 712 girls. Thus 54 per cent. of the whole number of pupils tested were boys. Therefore, if there is really a greater number of boys among the deficient, the proportion of boys in each degree of retardation, or on the average for all degrees of retardation greater than one year, *must be more than* 54 *per cent.* Any percentage less than this will indicate a preponderance of girls. Computation shows that in the class 4-7 years retarded, the proportion of boys is 58 per cent.; in the class 3 years retarded, the proportion of boys is 45 per cent.; in the class 2 years retarded, the proportion of boys is 56 per cent. If we average these three numbers we find practically no difference between the sexes, the average proportion of boys being 53 per cent. as compared with the 54 per cent. to be expected. Thus actually of the pupils from 2 to 7 years retarded, *there is a preponderance of girls* amounting to about 1 per cent. Goddard, however, considers real feeble-mindedness to be present only in those from 4-7 years retarded. And here there are 58 per cent. of boys as compared with the 54 per cent. to be expected.

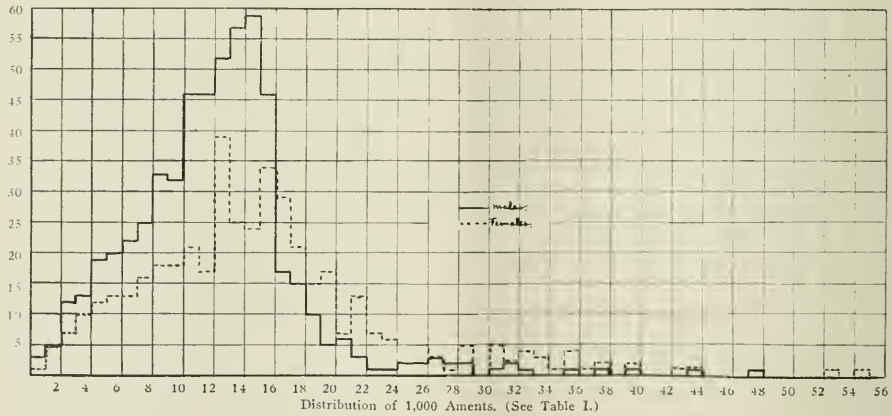
There is a larger preponderance of boys among those 1 year retarded than in any other degree of retardation, while their proportion among the normal is only 53 per cent., and 50 per cent. for each year of acceleration. There are *no* boys four years beyond their age, while there are two girls. These facts seem to indicate that Goddard's results are to some extent complicated by the earlier maturity of girls at the years nearest puberty. It is often stated that girls are more apt to be ahead of their actual age at puberty, and this would tend to leave the boys back a year or two.

The Present Investigation.—It was thought that light might be thrown upon this matter by a statistical investigation of defective individuals who pass through the Clearing House for Mental Defectives. The investigation was formulated with these questions in mind:

1. Is the frequency of mental deficiency greater among males than among females?

2. What have been the means of economic support in the case of those individuals, both male and female, who have survived outside of institutions till beyond the age of 16 years?

Method.—The procedure was as follows: 1,000 consecutive cases of mental defect were taken from the cases diagnosed at the Clearing House during the years 1912 and 1913. These cases included microcephaly, hydrocephaly, mongolianism, cretinism, Little's disease, birth palsy, idiopathic idiocy, idiopathic imbecility (mental and moral), idiopathic feeble-mindedness, and one case of porencephaly. The males and females were tabulated separately. In the case of individuals 16 years of age and over the means of economic support, the number of children known to have been propagated, and the immediate cause of appearance at the Clearing House were noted. In the case of all individuals the mental age (Binet) and actual age at examination were noted.



Distribution of 1,000 Aments. (See Table I.)

Results.—Of the 1,000 individuals thus tabulated, there were 568 males and 432 females. Of individuals over 16 years of age there were 78 males and 159 females. Of individuals over 30 years of age there were 9 males and 28 females. The curves found on this page show this distribution graphically. Both sexes show curves of distribution much skewed toward the high ages. For males the mode falls at 14-15 years; for females the mode falls at 12-13 years. At the age of 1-2 years the frequency for the sexes is equal. From 2 to 16 years the frequency for males is very much

greater than for females. At the age of 16 the curve for the females crosses that for the males, and from that point on the frequency for females is much greater than for males. The range for males is from less than 1 year to 47 years; the range for females is from less than 1 year to 54 years. Table III shows these facts in terms of per cent. and ratio.

TABLE I.—DISTRIBUTION BY ACTUAL AGE

Actual Age, Yr.	Males	Females	Actual Age, Yr.	Males	Females
0–1	3	1	28–29	2	5
1–2	5	5	29–30	0	0
2–3	12	7	30–31	1	5

18–19	10	15	46–47	0	0
19–20	5	17	47–48	1	0
20–21	6	7	48–49	0	0
21–22	3	13	49–50	0	0
22–23	1	7	50–51	0	0
23–24	1	6	51–52	0	0
24–25	2	5	52–53	0	1
25–26	2	5	53–54	0	0
26–27	3	0	54–55	0	1
27–28	2	1			

Table II shows the relation between mental age (Binet) and actual age at the time of examination at the Clearing House, for each sex separately. In some cases, because of language difficulty, blindness or similar circumstance, the patient did not take a Binet test and diagnosis was arrived at without this aid. Hence the number of cases treated in this table does not total quite 1,000. It will also be noticed that there are 4 males and 6 females who passed the Binet test for 12 years, and since the tests given at the Clearing House run only through 12 years, this shows an undetermined mentality. These individuals are included under the diagnosis of moral imbecile.

This table shows that for all mental ages the average actual age of examination at the Clearing House is older for girls than for boys—this difference becoming very marked after the mental age of 6-7 years. The figures show that a female with a mental age of 6 years survives in the social milieu about as well as does a male with a mental age of 10 or 11 years. The average deviations from the above averages are greater in all cases for females than for males, indicating that any boy of a given degree of defectiveness is much more certain to be brought at a given average age than is any girl of the same degree of defectiveness.

TABLE II.—SHOWING THE RELATION BETWEEN MENTAL AGE AND ACTUAL AGE AT THE TIME OF EXAMINATION

Mental Age, Yrs. (Binet)	Actual Age When Brought to the Clearing House					
	Males			Females		
	Average	A.D.	Cases	Average	A.D.	Cases
0–4	7.1	3.2	92	8.1	3.8	65
4–5	9.2	2.4	29	11.4	4.3	16
5–6	12.6	4.2	25	13.2	4.3	32

12+	13.0	0.0	4	16.8	2.9	6

TABLE III.—SHOWING, FOR EACH SEX, THE PERCENTAGE OF THE TOTAL NUMBER (MALE AND FEMALE) IN EACH FIVE-YEAR PERIOD OF ACTUAL AGE, SHOWING ALSO THE RATIO OF MALES TO FEMALES

	Under 5 Yrs.	5–10	10–15	15–20	20–25	25–30	30–35	Over 35	Tot. %
M....	7.2	15.8	26.0	5.3	0.9	0.8	0.4	0.4	56.8
F....	4.8	8.6	13.9	8.9	3.6	1.1	1.4	0.9	43.2
M–F.	1.5	1.8	1.9	0.6	0.3	0.7	0.3	0.5	1.3

Those individuals who survived in the social milieu till the age of thirty years and over constitute a group of peculiar interest from our point of view. On what economic basis had they lived all these years? And having so long survived, what was the immediate cause for their appearance at the Clearing House? The histories of these individuals give the following facts:

ECONOMIC STATUS OF THE 28 WOMEN OVER THIRTY YEARS OF AGE.

Married	9
Housework, living with relatives	9
Housework, for wage, always in very menial capacity	5
No economic status or occupation mentioned	5

IMMEDIATE CAUSE OF APPEARANCE AT THE CLEARING HOUSE OF THE 28 WOMEN OVER THIRTY YEARS OF AGE.

Illegitimate pregnancy (often the second or third)	6
Husband died	2
Husband abandoned	2
Accompanied their feeble-minded children to the Clearing House and were noted by physicians	2
Brought by those in charge of nurseries	2
Brought by social workers	5
Death or sudden incapacity of relatives	3
Specific disease	1
Complaint of minister	2
No immediate cause mentioned	3

ECONOMIC STATUS OF THE 9 MEN OVER THIRTY YEARS OF AGE.

Porter	1
Janitor	1
Chores at home	1
Transfer from almshouse	1
No economic status or occupation mentioned	5

IMMEDIATE CAUSE OF APPEARANCE AT THE CLEARING HOUSE OF THE 9 MEN OVER THIRTY YEARS OF AGE*

Disease	2
Drunkenness	1
Transfer or recommittal	2
No immediate cause mentioned	4

*It will be noted here that the number of men really surviving outside of institutions till this age is *only* 7, since there are two cases of transfer and recommittal.

The average mental age (Binet) of the 28 women over 30 years of age was 7.5, with an average deviation of 1.9; the average mental age of the 9 men over 30 years of age was 9.5, with an average deviation of 2.6. Thus females with an average mental age of 7.5 years survive in society at least three times as well as males with an average mental age of 9.5 years.

A matter of incidental interest is the number of children procreated by these feeble-minded individuals. In no case was there a history of procreation by the males, but the 159 females over 16 years of age had 44 children which were living and acknowledged, 31 of which were illegitimate, and 10 women were pregnant at the time of their examination at the Clearing House. Of these 159 women, furthermore, 16 were, or had been, married, 2 were engaged to be married, 2 were living with men to whom they were not married, 15 earned money by prostitution, and 56 were definitely known to have been victimized.

Interpretations.—The facts are as follows:

1. More males than females are brought to the Clearing House in a ratio of about 1.3:1.0.

2. At the age of 1-2 years the frequency for males and females is equal. From the age of 2 to the age of 16 there is a very marked preponderance of males. At the age of 16 years the curves cross

and from that point on there is a very marked preponderance of females.

3. Females survive in the social milieu till beyond the age of 16 years twice as frequently as males; females survive in the social milieu till beyond the age of 30 years three times as frequently as males.

4. The Binet measuring scale shows that for all mental ages the average actual age at examination is older for girls than for boys—this difference becoming very marked after the mental age of 6 years. The figures show, for instance, that a female with a mental age of 6 years survives in society about as well as a male with a mental age of 10 or 11 years.

5. The average deviations from the above averages are greater in all cases for girls than for boys, indicating that any male is much more certain to be brought to the Clearing House at a given average age than is a female of the same degree of defectiveness.

6. Of the 159 women over 16 years of age, the majority had had a more or less secure economic basis for survival either in housework or in prostitution.

These facts are interesting and significant for all who are immediately or remotely concerned with social problems. To interpret them we have but to reflect on our social organization. Women are not a competitive class. Their work is housework, performed in isolation and not in competition with others for a wage. Moreover, in our social organization, sex as such may easily become a commercial asset to women, and opens to them ways wherein they can survive without much regard to mental deficiency. Men, on the other hand, form a highly competitive class, working together in competition, for a wage. The boy who cannot compete mentally becomes at an early age an object of concern to relatives, is brought to the clinic and is directed toward an institution. The girl who cannot compete mentally is not so often recognized as definitely defective, since it is not unnatural for her to drop into the isolation of the home where she can "take care of" small children, peel potatoes, scrub, etc. If physically passable, as is often the case, she may marry, thus fastening herself to economic support; or she may become a prostitute, to which economic pursuit feeble mentality is no barrier. Thus they survive outside of institutions. Our data here reveal how accidental are the causes which finally bring them after thirty years to the Clearing House. The writer has frequently questioned those who accompany them when they come. Answers like these are typical: "Her husband has just died"; "She got rheumatism and can scrub no more"; "She was a prostitute, but physical illness has driven her from the street." No one can doubt that there are scores of feeble-minded women at large to whom these accidents have not happened.

Conclusion.—The greater frequency of amentia among males has come to be rather commonly credited and is sometimes cited as a proof of the greater variability of males. But all the facts gleaned from these data point to the conclusion that if social pressures had applied equally to male and female, enough additional females would have come to the Clearing House to equal the 568 males. The figures are certainly sufficient to suggest that if our social habit and organization ever changes so that sex as such is no longer of commercial and economic value to women, and so that women become mentally competitive to the same extent as men, the number of females in institutions for the feeble-minded will be materially increased.

THE TONSIL—A VESTIGIAL RESPIRATORY ORGAN.

By J. A. HAGEMANN, M.D.,

PITTSBURGH, PA.

If the postulate regarding the evolutional antecedents of the tonsil presented herein seems at variance with generally accepted views, the writer's defense must be that the theories were promulgated from the doctrines of foremost evolutionists, and that, reasoning from such premises, the conclusion arrived at appears tenable.

The tonsils are probably vestigial organs of respiration, a modified form of gills or branchiæ, surviving from the piscine and amphibious periods of man's descent; yet not deciduous, as were the gills of most amphibians that permanently abandoned aquatic habitats.

Darwin states that: "Still earlier the progenitors of man must have been aquatic in their habits; for morphology plainly tells us that our lungs consist of a modified swim-bladder, which once served as a float. The clefts on the neck in the embryo of man show where the branchiæ once existed."

Haeckel, in his "Evolution of Man," says: "The most important process we meet with in the further ontogenetic development of the intestinal canal in the human embryo is the origin of the gill openings. At the head of the human embryo, the wall of the throat very early unites with the outer wall of the body, and four openings then form on the right and left sides of the neck, behind the mouth, and these lead directly from without into the throat-cavity. These openings are the gill openings, and the partitions separating them are the gill-arches. These embryonic formations are very interesting; for they show that all the higher Vertebrates, when in a very young state, reproduce in accordance with the fundamental principle of Biogeny the same process which was originally of the greatest importance to the development of the whole vertebrate tribe. This process was the differentiation of the intestinal canal into two sections: an interior, respiratory part, the gill-intestine, which serves only for breathing, and a posterior, digestive part, the stomach-intestine, which serves only for digestion.

* * *Afterwards, however, the gill-intestine, which is a memorial of the fish-ancestors, as such, is entirely lost. The parts that remain take a wholly different form; but notwithstanding that the anterior section of our intestinal canal thus surrenders entirely its original form of gill-intestine, it yet retains its physiological function as a respiratory intestine."

Haeckel also says in "The Wonders of Life": "In the lower aquatic vertebrates (acrania, cyclostoma,

and fishes) the gills are the sole organs of breathing; in the higher animals, that live in the air, they fall into disuse, and their place is taken by the lungs. Nevertheless, heredity is so tenacious that we find from three to five pairs of rudimentary gill-clefts in the embryo right up to man, though they have long ceased to have any function. This is one of the most interesting of the palingenetic facts that prove the descent of the amniotes (including man) from the fishes."

When man's progenitors periodically forsook the waters, the organs we now know as lungs gradually developed from the swim-bladder and, *pari passu*, the gills, not being required during protracted periods, would cease to functionate and would become noticeably atrophied. Yet we can conceive that in consequence of subsequent inundations, or to escape attack by terrestrial pursuers, countless successive generations of these amphibious creatures would intermittently be compelled to resume aquatic habits temporarily, thereby again requiring the functions of the gills as oxygen transmitters. It is reasonable to suppose that unnumbered repetitions of this experience, extending over countless æons, would eventually develop a faculty of regenerating gills, and adjusting their forms and functions to the respective prevailing conditions, eventually resulting in the form of an irregular ovoid body set between a pair of practically parallel muscles, the palatoglossus and palatopharyngeus, known to us with their coverings as the anterior and posterior pillars of the pharynx. These muscles, in man, are supplied by branches from the facial nerve, whose function is largely motor. Contraction and relaxation of these muscles, in the amphibious stage, would result in alternate compression and release of the tonsil, with consequent pumping in and out of the circumfluent water. Examination of the tonsil in its present rudimentary form, particularly as seen in children, reveals a smaller or larger body, dotted with mouths of crypts whose cavities are lined with epithelium. Surely it is not a wild flight of fancy to imagine that the object of this arrangement was to present a greater surface to the water which swirled through the throat, thereby giving additional opportunity to absorb the necessary oxygen. In man, the tonsillar bodies are supplied by branches from the trigeminus and glossopharyngeus nerves, both of which may be traced to the lateral columns of the medulla into the region of the reputed respiratory center, which also might imply a former respiratory function.

When the tonsils have been incompletely removed in very young children there is a marked tendency to regeneration, reminding one of the salamander, who regenerates a leg or an eye so long as there is a fragment of the original left from which the new growth may spring. While the cases are not parallel, both indicate a tendency to restore an organ which may again be necessary to sustain life in the face of hazardous exposures which innumerable progenitors had survived. Only such salamanders remained alive to propagate their species as were able to regenerate a leg or an eye; those unable to do so soon perished and left no descendants. Only those progenitors of man who retained rudimentary gills could continue their existence when a tidal wave washed them off some rocky shore back into their ancestral watery home. Those whose lungs had already become their sole oxygen supplying organs were incontinently drowned. In this manner, when the world was younger, and the waters periodically overflowed the land, a natural selection took place; those individuals who could successfully bring their rudimentary gills into action surviving their more unfortunate brethren. Through incomprehensible periods of time and incalculable repetitions of such experiences an innate faculty of regenerating an "under water" breathing organ was developed which rudimentarily still persists in man, although he has long since become solely a lung-breathing animal by reason of the great changes in the topography of the earth's surface.

This seems to offer a reasonable explanation of the phenomenon frequently seen when an imperfectly removed tonsil shows a tendency to regenerate rapidly. Nature appears to rush to the rescue from force of habit. Only possessors of tonsils survived; and so long was this a law of experience that nature has not yet unlearned the lesson.

If these random thoughts should stimulate some other to delve deeper into a subject the surface of which has only been touched in this paper, the writer will feel amply recompensed.

Highland Building.

Medicolegal Notes.

Privileged Communications—Assisting Surgeon.—In an action for personal injuries it appeared that the attending physician deemed a surgical operation necessary, and called another physician or surgeon to assist in performing the operation. Upon the trial the facts and circumstances which led up to and rendered the operation necessary were brought in issue. It was held that any information acquired by the assisting physician at the operation or subsequently acquired by examination of the parts removed by the operation was privileged information under the provisions of Section 5958 of the Idaho Revised Codes, and could not be given in evidence without the consent of the patient.—Jones v. City of Caldwell, Idaho Supreme Court, 130 Pac. 995.

Stepfather's Liability for Professional Services.—In an action for physician's services it was held that the defendant was liable for services rendered to his stepchild who lived with him, although the child's father was alive, and, on divorce from the child's mother, had been ordered to pay her $5 monthly during the child's minority for its support. The defendant stood in the position of parent to the child and was liable under the principle that the law implies a promise where a parent with full knowledge of the facts and without objection allows and approves of his child being furnished with necessaries.—Monk v. Hurlburt, Wisconsin Supreme Court, 138 N. W. 59.

Accepting Gifts from Patients.—In an action to set aside a deed it was held that the relation of a physician to his patient is one of trust and confidence, and while it does not forbid acceptance of a gift or conveyance from the patient, the burden of establishing perfect fairness, adequacy and equity is thrown upon the physician. A confidential adviser is not permitted to avail himself either of the necessities of his client or his good nature, liberality, or credulity to obtain undue bargains.—Matthaei v. Pownall, Pennsylvania Supreme Court, 84 Atl. 444.

Observations Made by X-Rays as Evidence.—A witness who has qualified as an expert in the use of the *x*-ray and fluoroscope may be permitted to give the result of his observations, notwithstanding such observation discloses the shadow of the object, and not the object itself. *X*-ray photographs, sciagraphs or radiographs, which are no less representative of the shadow and not the substance, are properly admissible in evidence.—McCauley v. Chicago City Ry. Co., 163 Ill. App. 176.

State Board of Medical Examiners Performs Ministerial Duty.—The Oklahoma Supreme Court holds that the state board of medical examiners in hearing charges filed before it pursuant to Comp. Laws, 1909, Sections 4242-4264, for the purpose of having revoked a license theretofore issued by it to practice medicine and surgery in the state, on the ground that the same had been obtained through fraud, and also charging the certificate holder with unprofessional conduct, is engaged in the performance of a ministerial duty, and does not exercise judicial power, and a writ of prohibition thereto will not lie.—Janneson v. State Board of Medical Examiners, 130 Pac. 923.

THE ETIOLOGY OF GASTRIC ULCER.

THE etiology of gastric and duodenal ulcer has been one of the standard mysteries of medicine for many years. Recent years have served to throw some light on the question and with the aid of animal experimentation we are now able to see at least a little way into the darkness. Aschoff has shown that ulcer of the stomach generally begins as a hemorrhagic erosion and has presented beautiful demonstrations of the manner in which the ulcer develops. That the immediate cause of the hemorrhagic erosion may be found in a thrombosis of some of the finer vessels must be admitted. The stomach is furnished with such ample blood-supply that ligation of many of its vessels may be performed without disastrous results. Thrombosis or embolism of the finer twigs nevertheless results in the production of an infarct and from this may develop an ulcer. The source of such thrombosis or embolism is undetermined, but it has been produced experimentally, and while the work is far from complete enough has been done to point a definite road for further investigation.

D. P. D. Wilkie, in pursuing this study (Laboratory Reports of the Royal College of Physicians, Edinburgh, vol. xii), operated upon cats and rabbits and dissected the human cadaver. He found that in infancy the veins of the portal system are provided with competent valves but that with age the great majority of these become incompetent. After these valves no longer serve to regulate the blood flow through the veins in which they are situated there is a rather frequent tendency to an "oscillation" of the blood in the portal vessels. Under the influence of changes in the blood-pressure, respiratory movements, or the distention of the stomach with food, the blood returning from the omentum may be diverted from its usual course and may traverse the gastric venous plexus, which thus comes to act as a filter for the omental blood. After a study of the omentum, Wilkie concludes that one of the important functions of that tissue is to aid in the localization of peritoneal inflammation and that in the performance of this function it is apt to suffer injuries from which it does not fully recover. He was able to demonstrate that thrombosis occurs readily in the thin-walled veins of this tissue and believes that thrombi in such a mobile situation would easily become broken up. In order to test out his hypothesis he produced thrombi in the omental veins by means of a simple ligation or by searing the tissues alongside the vein with a hot platinum needle. Later he produced artificial emboli by injection into the veins of emulsions of charcoal or dermatol in oil. The animals were killed in from three to seven days after the operation and careful autopsies performed. In every instance he found numerous minute infarcts in the liver, thus showing that embolism had taken place along the normal blood course in the portal system. In a certain percentage of his animals he found in addition that there were multiple hemorrhagic erosions in the gastric mucosa. In addition to the erosions there was in three instances definite ulceration of the gastric mucosa and one animal showed an ulcer of the duodenum. These ulcers were punched out, sharply circumscribed areas and similar in every way to the acute gastric ulcer found in man. Microscopic examination showed that beneath the ulcerated area in the mucosa the minute vessels were thrombosed and that the thrombi moreover contained charcoal or dermatol when these substances had been injected into the omental veins.

It is known that in the course of attacks of acute or chronic appendicitis the patient not infrequently suffers from hematemesis and the same occurrence has been reported following a herniotomy in which it was necessary to remove a portion of the omentum. It is known also that there is a certain class of patients who suffer from symptoms referable entirely to the stomach but in whom at operation the only lesion demonstrable is a chronic appendicitis. The relation to the above experiments would seem to be quite close. Indeed, one is almost forced to the conclusion that injury to the omentum or its involvement in an inflammatory process has provided a source for emboli whose lodgment in the stomach has so injured the mucous membrane as to give rise to hemorrhages. There is no reason to suppose that similar emboli might not come from other veins in the portal system and that a continued insult of the stomach from, say the appendix, might not bring about secretory changes in the stomach, thus giving rise to the symptoms from which these patients suffer. It is admittedly going too far to say that all ulcers are caused in this manner and there must be many contributing causes which tend to alter the character of the lesion. The work is really only begun. The lesions found have been acute ulcers which show a persistent tendency toward healing. It would be interesting to know what effect such thrombosis has upon the character of the gastric secretion and if the course of the ulcers could be influenced by bacterial infection. The animals should be allowed to live for longer periods of time to see if in some instances the ulcers might not become chronic. The field is a broad one and important. The treatment, both medical and surgical, of ulcer of the stomach and duodenum is in the highest degree unsatisfactory and any help will be welcome.

THE HARDENING OF CHILDREN.

A topic that has received considerable attention in the popular hygienic books and journals and that appeals with particular force to the average parent is the hardening of children. The theory upon which this belief is based holds that a certain amount of exposure to cold and wet is a good thing for the child and serves to protect it subsequently against many ailments caused by sudden changes of temperature. The physician is frequently asked to express an opinion on this subject and it is quite likely that in most instances he will hesitate before giving an answer, which is more apt to be vague than definite. The reason for this is that the risks of an injudicious method of hardening are greater than those of a careful nurture of the young. The specter of rheumatic endocarditis more than counterbalances the virtue of wet feet, of bare knees, and of gauze underwear. There are so many factors to be considered: the individual child, the climate, the season, and the environment, that the problem of hardening becomes one of careful study and deliberation, rather than one of vague generalization. The question may be asked: are there any accurate scientific data upon which one may base a rational method of hardening? Fortunately an affirmative answer is available.

The subject of hardening is discussed in its broader physiological and clinical aspects by Alois Strasser in the *Zeitschrift für physikalische und diätetische Therapie,* July, 1913. He emphasizes the necessity of this hardening, but it should be accomplished with due regard to the age and constitution of the child. The fact should be borne in mind that the surface covering of the child with reference to the latter's weight is an extensive one, and that the tendency to loss of heat and the irritability of the nervous system are greater than in the adult. These circumstances decree that rigid systems of hardening are not only unnecessary but may be of distinct danger. Neither during the first few weeks of life, nor at any rate during the first years, can the child tolerate a hydrotherapeutic process of hardening. For the first few years of life the open-air method of hardening is the more important. The question is not so much one of exposure to the ever-varying changes of the outer air as one of adaptation of the uncovered skin to the atmospheric temperature variations of indoor air, and the adaptation of the body suitably clad to all sorts of weather outdoors. Pouring cool water over the child while the latter is in a lukewarm bath is more a process of stimulation than one of hardening, and it is of no great importance if the daily bath, which at any rate should not be too warm, about 90° F., is cooled a few degrees while the child is in the bath. Mild hydrotherapeutic measures may be employed in the case of children three or four years of age, but these measures should not go beyond a mere sponging of the body. Showers and douches of low temperature are at this age detrimental. The morning hours are the best for giving the sponge bath, unless definite therapeutic indications, such as insomnia and enuresis, demand that the bath be given in the evening.

During the later years of childhood up to puberty the order in the carrying out of hydriatic procedures is of greater moment than a mere intensification of the latter. As a rule a single short stimulating bath in the morning is sufficient, and this must be adapted to the susceptibility of the child. Safety and comfort are the criteria upon which the mode of bath should be based. Physiological observations have shown that psychic influences, such as fear, have a profound influence in changing and even in reversing the physiological effect of thermic stimuli.

With reference to the age of the child an important point is emphasized by Strasser. During the period of growth there are certain stages of rapid increment of organic development, during which the body needs all of its resources for growth and during which any excessive strain upon the nervous system, upon the heat-regulating mechanism, etc., is apt to produce disastrous consequences. These periods of rapid growth are between the fourth and fifth, the ninth and tenth, and the thirteenth and fourteenth years of life, and particularly in the girl at the time of puberty. During these critical periods one should be particularly cautious in carrying out any hardening measures.

MIXED DIET AND METABOLISM.

While it has always been recognized that a mixed diet embracing all the food elements was a necessity for the maintenance of health and for good nourishment, yet it is only since the recent studies in metabolism that this precept has been given definite foundation. Nature intended, in the creation of the many articles of food, that they be partaken of in variety. The overconsumption of one food product overworks the organs concerned in its utilization to exhaustion, after which they can no longer perform their functions properly. In this way the overconsumption of carbohydrates for only a temporary period causes a transient glycosuria, because the organism cannot convert and utilize the overplus. The organ concerned in the utilization of carbohydrates is the pancreas. If the overfeeding is temporary the pancreas accommodates itself to this, and gives warning through the glycosuria, but after continual abuse, and disregard of these warnings, there is exhaustion damage of a permanent nature, and diabetes. This is the carbohydrate theory of diabetes.

On the other hand, the overingestion of proteins may have the same effect, especially if accompanied with an unphysiological quantity of carbohydrate. Besides, it is now understood that protein and fat are themselves prolific sources of sugar, and help to augment the quantity actually taken into the body in the form of carbohydrates. Overindulgence in protein causes an overproduction of the toxic albuminoids, the end-products of protein digestion, and acids, like uric acid, which have to be rendered innocuous by the liver, but especially the pancreas. Incomplete combustion of this excess protein matter results in the production of such acids as acetone, diacetic acid, and β-oxybutyric acid, which, as we

know, are present in other toxemias besides diabetes. With an undamaged pancreas and normal sugar utilization, these bodies are converted in the presence of utilized carbohydrates, which act as catalytic agents, into carbon dioxide and water, and thus rendered harmless. The acids, even if not of the acetone variety, render the blood underalkaline, and manifest themselves in disturbed nutrition, indigestion, and the symptom complexes commonly classed under the heading, irregular gout.

Another phase of this lack of a mixed diet manifests itself, however, not so much in a want of variety in the food elements, as in a lack of variety in the articles of food consumed. While the former condition is common in the richer classes, the latter is the rule in the poorer. These subsist on the same articles of diet year in and year out; they can predict their menu a year in advance. Contrary to the general opinion the quantity of food is not small, yet these people are spoken of as undernourished and underfed. Food variety satisfies the appetite in smaller total quantities than a larger total quantity of one article of diet. The natural repulsion felt toward sameness in food is merely an expression of the organism's intolerance of it. This repulsion can perhaps be accounted for on the theory of anaphylaxis. Anaphylaxis is the increasing susceptibility or intolerance acquired by the organism to the same substance or toxin. Anaphylaxis has, moreover, been used to explain the untoward symptoms of intoxication in certain individuals after ingestion of certain articles of food. The end-products of every food, while essentially similar, if composed of the same food elements, have their own peculiar characteristics and it is possible that the organism acquires an increasing intolerance to the ever same end-products. Or the intolerance may be an inability to assimilate, resulting in anemia, malnutrition, and asthenia. For such individuals a change of diet, even without regard to the component food elements, is essential.

MODERN TREATMENT OF GENUINE EPILEPSY.

The number of remedies, old and new, which are able in some degree to decrease the number of epileptic paroxysms is very large, and includes many sedatives, hypnotics, narcotics, antispasmodics, etc. These effects are also genuine because suggestion should play little or no rôle in the therapeutics of this disease. Other substances, the mode of action of which we know nothing, are also efficacious. Of late years much labor has been devoted to preparing patented remedies containing the most efficacious anticonvulsives, just as in prebromide days physicians used to combine in one formula belladonna, valerian, zinc, etc.

Hence to be able to sum up in a few broad strokes just which of all alleged remedies excel the rest should be the task of a man incessantly at work at all aspects of the subject; such as Jödicke, for example, a prolific writer. At a session last spring of the Wissenschaftlicher Verein der Aerzte zu Stettin (*Berliner klinische Wochenschrift,* September 22) this author naturally gives first praise to the halogens—bromides and chlorides—for in addition to clinical experience we have recently learned that the rationale of the bromide medication is bound up with the reciprocal relations between Br and Cl. Jödicke lays much stress on the use of bromides in cookery. The chlorides, administered in all forms, internally and externally, are the natural remedies for bromism. The mortality of status epilepticus has been brought down from 10 per cent. to 0 by a combination of rest, amylene hydrate enemata, venesection, and saline infusion. A new patented substance has been shown to exert a powerful influence on the most severe types of convulsions, but it produces such severe collateral effects as not to be utilizable.

Indications for Inferior Bronchoscopy.

As is well known many specialists do not practice superior bronchoscopy because of the possibility that even with strictest indications and technique subsequent tracheotomy will be required, and the simpler operation with inferior bronchoscopy may therefore be preferable as a routine procedure. Friedrich of the Medical Society of Kiel reported a case last summer to illustrate this point (*Muenchener medizinische Wochenschrift,* September 23). The patient was a boy aged 5 who had swallowed a carpet tack. The symptoms were mild and an *x*-ray examination located the foreign body at the left sternal margin and fourth rib. Superior bronchoscopy, done under narcosis with patient seated, eliminated the left bronchus. Succeeding examinations of both kinds then located the object in the right middle bronchus. As upper bronchoscopy had now become difficult, much mucus having accumulated, the operation of tracheotomy was done and a tube passed directly into the right middle bronchus. Through the tube the nail was grasped and everything was drawn out at once. The tack was half an inch long, with a flattened head about one-third of an inch in diameter. A considerably larger tube can be used in inferior bronchoscopy.

Radioactive Waters

So much is being said now in the newspapers regarding the therapeutic uses of radioactivity that a warning recently issued by the Bureau of Chemistry against possible misrepresentation in the advertising of radioactive mineral waters is timely. The Department of Agriculture is now investigating a number of so-called radioactive waters with the object of securing evidence that can be made a basis of prosecution for misbranding. Some of these bottled waters are, as they came from the ground, radioactive, but this property is due almost entirely to radium emanation and is rapidly dissipated. The department's circular states that if the radioactivity of a water at its source is 100, four days after bottling it will be only 50, twelve days after bottling 10, and in a month practically nothing. It is evident, therefore, that any water, the therapeutic efficacy of which depends wholly or in part upon its radioactivity, must be taken at the spring, and if it acts at all in a curative way, when bottled, this activity will depend upon its contained salts and not upon its radioactivity. The officials of the Bureau of Chemistry fear that a fraudulent trade in so-called radioactive waters will develop, just as a fraudulent trade in other mineral waters was de-

veloped some time ago, to the point where people with strong imaginations will supply the bottlers with testimonials asserting that these waters have effected wonderful cures. Hence the issuance of a warning to the public.

Quarterly of the Federation of State Medical Boards.

We have received the first number of this journal which, as its name indicates, is the organ of the newly established Federation of State Medical Boards. It is under the editorial charge of Dr. Otto V. Huffman, secretary of the Federation, and also of the New York State Board of Medical Examiners. Although primarily intended for the convenience and information of members of the various State licensing boards—and the first number gives promise that this function will be well performed—the journal contains much that will hold the attention of all interested in medical education. "Preparation for the Professions," by Henry S. Pritchett; "The Homœopath's Viewpoint of Medical Education," by Royal S. Copeland; "Chief Needs and Functions of the Federation of State Medical Boards," by N. P. Colwell; "An Address to State Boards," by W. A. Spurgeon; "Uniform State Laws—a Necessity," by Charles Thaddeus Terry; "Rules and Regulations Governing Examinations," by John M. Baldy; "Discipline of the Character in Medical Education," by Eugene A. Philbin, and "Universal Reciprocity," by Beverley D. Harison, are the articles in this first number. In addition it contains the constitution and by-laws and a list of charter members and fellows of the Federation, news notes, excerpts, and editorials. Much is hoped from this association in the way of unifying medical laws and standardizing State examinations, all of which must be preliminary to universal reciprocity, and the *Quarterly*, if conducted on the lines and in the way shown forth in its first issue, will be of invaluable service in furthering these ends.

News of the Week.

Report on the Canal Zone.—The Department of Sanitation of the Isthmian Canal Commission reports that during the month of August, 1913, the total number of deaths from all causes among employees was 39, of which 21 were due to disease and 18 to violence, giving an annual average death rate of 8 per thousand for the month, which is two points lower than the rate for the same month in 1912. Including both employees and civil population the annual average death rate per thousand in the cities of Panama and Colon and the Canal Zone for the month was 24.23, a slight decrease as compared with last year. Among employees the principal causes of death were the following: Lobar pneumonia, 4; malarial fever, 3; pulmonary tuberculosis, 3; abscess of the liver, entamebic, 2. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

Hospital Dedicated.—The new wing of the Misericordia Hospital on East Eighty-sixth Street, New York, was dedicated on October 13 by Cardinal Farley. The addition of this wing, which provides for 275 beds and will be used for surgical cases, makes the hospital the second largest Roman Catholic hospital in the city.

International Anti-Tuberculosis Association.—Under the patronage of the Empress of Germany the Eleventh International Anti-Tuberculosis Conference was held in Berlin on October 22 to 25. For the general meetings the program was divided into four parts: (1) Tuberculosis and Mankind, discussed by Prof. Landouzy of Paris, Prof. T. Shennan of Edinburgh, and Prof. Franz Hamburger of Vienna; (2) "The Surgical Treatment of Tuberculosis of the Lungs," discussed by Dr. Brauer of Hamburg, and Dr. Tuffier of Paris; (3) "The Influence of Insurance in Anti-Tuberculosis Work: Private Life Insurance," by Dr. Lee K. Frankel of New York; "Mutual Insurance," by Dr. Emile Fuster of Paris; and "State Insurance," by Prof. Kaufmann and Prof. Koch of Berlin; (4) Schools for Pretuberculous Children, by Prof. Blumenthal of Moscow, Dr. Chaptel of Paris, and Prof. Franz of Berlin. Twenty-six national societies are now included in the association.

Personals.—Dr. Joseph W. Moore of the Manhattan State Hospital, Ward's Island, N. Y., has recently been appointed first assistant physician at the Matteawan State Hospital.

Dr. D. Bryson Delavan, his many friends will be rejoiced to learn, has completely recovered from the serious illness and operation from which he suffered last spring, and has resumed practice at 40 East Forty-first street.

Col. William C. Gorgas, chief sanitary officer of the Canal Zone, arrived in New York on Monday of this week. He is on a leave of absence to go to South Africa to direct the sanitation in the mines where 200,000 natives are employed and where the mortality is excessive.

Dr. John R. Slattery of Boston, physician-in-chief to St. Elizabeth's Hospital in that city, has been honored by Pope Pius X, who has created him a Knight of the Holy Sepulchre.

Mr. Frederic B. Morlock, for the past ten years chief clerk and assistant treasurer at the Presbyterian Hospital, New York, has recently been appointed superintendent of the Flower Hospital, which for the past six months has been under the direction of an acting superintendent.

Prof. Carl Voegtlin, associate professor of pharmacology in Johns Hopkins University, has been appointed professor of pharmacology in the Hygienic Laboratory, United States Public Health Service, Washington, to succeed Prof. Reid Hunt who recently resigned to accept the chair of pharmacology in the Harvard Medical School. Dr. Voegtlin's work has covered researches in pathological protein metabolism, the treatment of tetany with calcium salts, the function of the liver in anaphylaxis and jaundice, etc., and he will continue along these lines in his new field.

Dr. Richard Lewisohn of New York City has moved his office to 565 Park avenue.

Charitable Bequests.—The will of the late Mr. Benjamin Altman of New York, who died on October 7, distributes an estate of about $50,000,000 largely for public purposes. In addition to the bequest of his invaluable art collection to the Metropolitan Museum, donations to charitable institutions in New York City were made as follows: To Mount Sinai Hospital, $100,000, to be kept as a separate fund, one-half of the income thereof to be used for the benefit of the department of nervous diseases, and the remainder for the general purposes of the hospital as the directors may deem best; and to St. Luke's Hospital, the German Hospital and Dispensary, the New York Eye and Ear Infirmary,

and the Lincoln Hospital and Home, $25,000 each for the general purposes of the institution.

By the will of the late Miss Rebecca L. Bringhurst of Philadelphia, the University of Pennsylvania receives a bequest of $15,000 to be used to endow three beds in the orthopedic ward of the University Hospital.

By the will of the late Mrs. Mary L. Parsons of New York, the New York Post-Graduate Medical School and Hospital receives a bequest of $2,000.

Mt. Sinai Hospital, the German Hospital, and the Montefiore Home receive bequests of $2,500 each by the will of the late Max E. Bernheimer of this city.

A number of charitable institutions are remembered in the will of Mr. Samuel J. Silberman of New York, who died recently. The Beth Israel Hospital receives $5,000; Mt. Sinai Hospital, $2,500; Lebanon Hospital and the Montefiore Home, $1,500 each; Hospital for Deformities and Joint Diseases, Har Moriah and the National Jewish Hospital for Consumptives, Denver, $1,000 each.

Cedar Valley-Austin Flint Medical Society.—This society will assemble for a two-day sessions in Fort Dodge, Ia., on November 10.

Holyoke Medical Association.—The annual meeting was held in Holyoke on October 3, when officers for the ensuing year were elected as follows: *President,* Dr. J. J. Carroll; *Vice-President,* Dr. Forrest L. Leland; *Secretary-Treasurer,* Dr. Fred H. Allen.

New Home for Nurses.—A home for the nurses of the Women's Homeopathic Hospital of Philadelphia, recently erected at a cost of $35,000, was formally opened on October 15 with appropriate exercises. The building is colonial in architecture, three stories high and constructed of brick and stone. It will accommodate about 35 nurses.

City Death Rate.—The death rate for the week ending October 11 in New York City was 12.63 per 1,000 of population, representing a total of 1,301 deaths, as compared with a rate of 14.05 per 1,000 and a total of 1,393 deaths for the corresponding week of last year. Because of the epidemic of typhoid fever on the East Side, 27 deaths due to that disease were reported, an increase of 80 per cent. over the same week of 1912.

Vermont State Medical Society.—The 100th anniversary of this society was marked by the three days' annual convention in Burlington, October 8 to 10. The following officers were elected for the coming year: *President,* Dr. A. Lawrence Miner, Bellows Falls; *Vice-President,* Dr. Grace Sherwood, St. Albans; *Secretary,* Dr. J. M. Hamilton, Rutland; *Treasurer,* Dr. Charles F. Dalton, Burlington.

Wisconsin State Medical Society.—At the annual meeting in Milwaukee on October 2 to 4, Dr. Charles S. Sheldon of Madison, who had already served the society as secretary for 25 years, was elected president. The following vice-presidents were also elected: Dr. Curtis A. Evans, Milwaukee; Dr. C. J. Combs, Oshkosh, and Dr. E. Kinne, Elkhorn. The other officers will be elected by the Councilors in January.

Medical Association of the Southwest.—The following officers were elected at the annual meeting of this association in Kansas City, Mo., on October 8: *President,* Dr. Samuel S. Glasscock, Kansas City; *Vice-Presidents,* for Missouri, Dr. J. D. Griffith, Kansas City; for Texas, Dr. J. D. Dodson, Vernon; for Oklahoma, Dr. D. A. Meyers, Lawton; for Arkansas, Dr. L. R. Ellis, Hot Springs; *Secretary-Treasurer,* Dr. Frederick H. Clark, El Reno, Okla.

Obituary Notes.—Dr. William B. Zineman of Philadelphia, a graduate of the Baltimore University School of Medicine in 1896, died at his home recently.

Dr. Robert L. Brodie of Charleston, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1849, a medical director in the Confederate Army during the Civil War, and a member of the American Medical Association and the South Carolina State and Charleston County Medical Societies, died at his home on October 2, aged 84 years.

Dr. William John Bradley of Cedar Rapids, Ia., a graduate of the Rush Medical College, Chicago, in 1890, and a member of the American Medical Association and the Iowa State and Linn County Medical Societies, died at his home from typhoid fever, on October 2, aged 47 years.

Dr. John N. Merrill of Skowhegan, Me., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1869, a veteran of the Civil War, and a member of the Maine State and Somerset County Medical Societies, died at his home, after a brief illness, on October 2, aged 71 years.

Dr. Charles Sinclair Elliott of Kansas City, Mo., a graduate of the Pulte Medical College, Cleveland, O., in 1886, professor of nervous and mental diseases in the Kansas City Hahnemann Medical College, and author of several medical text-books, died at his home on September 27, aged 50 years.

Dr. L. V. White of Marathon, Tex., a graduate of the Southern Medical College, Atlanta, Ga., in 1886, died at his home, after a brief illness, on September 30.

Dr. Horatio Henry Brown of Jackson, Tenn., a graduate of the Lincoln Memorial University, Medical Department, Knoxville, Tenn., in 1899, died suddenly from uremic poisoning at his home on October 7, aged 42 years.

Dr. Jonathan Burmond Garber of Dunkirk, Ind., a graduate of the Jefferson Medical College, Philadelphia, in 1890, and a member of the American Medical Association and the Indiana State and Jay County Medical Societies, died at his home from injuries sustained in an automobile accident, on October 3, aged 57 years.

Dr. Robert Lyon Sanderson of Sparta, Ont., a graduate of the Cleveland University of Medicine and Surgery, Cleveland, O., in 1857, and for many years medical officer of the township of Yarmouth, died at his home on September 30, after a long illness, aged 81 years.

Dr. S. S. Huber of Brooklyn, N. Y., a graduate of the Jefferson Medical College, Philadelphia, in 1865, died at his home on October 16, aged 76 years.

Dr. Howard Patterson of Philadelphia died at Jefferson Hospital on October 15 as the result of an operation at the age of 63 years. He was graduated from Jefferson Medical College in the class of 1874, and after practising his profession for a short period at Stroudsburg, Pa., he returned to Philadelphia. He was a Mason of high rank.

Dr. Charles B. Jennings died at Reading, Pa., on October 11 at the age of 57 years. He was graduated from Hahnemann Medical College and Hospital of Philadelphia in the class of 1881. He was for fifteen years a member of the Reading School Board and he was recently appointed a member of the local Board of Pension Examiners.

Dr. L. H. Hartsell of Youngstown, O., died of scarlet fever at Philadelphia on October 12, while serving as interne in the Municipal Hospital for Contagious Diseases. He was graduated from Jefferson Medical College in the class of 1912.

Dr. C. S. Britton of Smithville, S. C., a graduate of the Medical College of South Carolina, Charleston, in 1885, died at his home on October 10, aged 70 years.

Dr. James H. Snowden of Center Ridge, Ark., died at his home on October 7, aged 65 years.

Dr. William H. Wathen, LL.D., of Louisville, Ky., a graduate of the University of Louisville, Medical Department, in 1870, a member of the American Gynecological Society, one of the founders and for many years dean of the Kentucky School of Medicine, which in 1908 was merged with the Medical Department of the University of Louisville, and since that time professor of abdominal surgery and gynecology in the latter institution, died at St. Anthony's Hospital, Louisville, after a short illness, on October 7, aged 67 years.

Dr. Hiram Raleigh Kennedy of Green Hill, Ala., a graduate of the University of Louisville, Medical Department, Louisville, Ky., in 1879, died at his home on October 7.

Dr. William F. Minard of Waterbury, Vt., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1887, died at the Massachusetts Homeopathic Hospital, Boston, on October 9, aged 46 years.

Dr. Timothy Miles Leatherwood of Tuscaloosa, Ala., a graduate of the University of Alabama, Medical Department, Mobile, in 1891, and a member of the Alabama State and Tuscaloosa County Medical Societies, died at Asheville, N. C., after a long illness, on October 8, aged 50 years.

Correspondence.

THE TREATMENT OF RHEUMATISM.

To the Editor of the Medical Record:

Sir:—Most physicians give the salicylates in the treatment of acute rheumatism. In fact it has been said that anything which does not yield to the salicylates is not rheumatism. The longer I practise medicine and the more I observe the disease, the more I come to look at it in that same light myself. I look upon those so-called cases of rheumatism that last three months and six months and possibly become chronic as not rheumatism at all. They are a good deal more apt to be septic in nature and would be more likely to yield to antistreptococcus or some other serum if the exact nature of the offending germ could be determined. It matters not what form of salicylate is taken, it is absorbed as salicylate of sodium. When it gets into the system it breaks up and salicin unites with the uric acid and is eliminated as salicyluric acid. But what becomes of the sodium? This does not vanish as a dream!

In the blood of a rheumatic patient there is present lactic acid. That lactic acid is the cause of the symptoms can be readily demonstrated by injecting enough of it into the veins of an animal to render the blood anywhere near neutral, when the animal will show signs of pain. It is my opinion, and simply my opinion, for I have no authority for this statement, that the lactic acid unites with the sodium and is eliminated as lactate of sodium. If this is so, it would seem that the proper treatment of rheumatism would be to take a teaspoonful of baking soda in a half glass of water at meals. But here comes the trouble: the stomach in health contains hydrochloric acid and the minute this meets bicarbonate of sodium it forms sodium chloride, and salt will not cure rheumatism. The rectum is alkaline, neutral, and occasionally slightly acid. For a long time I have treated rheumatism by injecting bicarbonate of sodium into the rectum. I dissolve one teaspoonful of bicarbonate of sodium in one glass of water and every twenty minutes inject one ounce into the rectum with a glass syringe. I wish others would give the treatment a trial.

Geo. W. Greene, M.D.

Auburn, N. Y.

THE CAUSE OF MIGRAINE.

To the Editor of the Medical Record:

Sir:—Permit me to refer concerning migraine to my report in the *Post-Graduate*, 1903, IV, 504, demonstrating that these temporal hemicranias, migraine, tic, etc., are usually, if not always, reflexes depending upon, and originating from, variously formed hypertrophies of the septal mucous membranes, situated at the lower border, or just beneath the expansions of the olfactories. Two severe cases are cited out of many milder. Miss K., age 23, a sufferer from these neuralgias since earliest childhood and worst on the left side, presented these hypertrophies on both sides of the septum. They were much larger on the left side, posteriorly nearly three-eighths of an inch thick, puffy. Cauterization, under cocaine, of the left side first relieved the pains on this side promptly and four weeks later she returned for treatment of the right side. A young man, 25, had for years pains on the left temple of sufficient severity temporarily to incapacitate him for business. Cauterization of the very large hypertrophies on the left side relieved him and there was no return in two years. In explanation the centripetal course would seem to be through the superior maxillary branches of the fifth through Meckel's ganglion into the temporal expansions of the inferior maxillary, but because of at times accompanying occipital and frontal neuralgias higher centers may become irritated.

C. Am Ende, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPENING SESSION—CHANGES IN HOSPITALS AND SCHOOLS—INTRODUCTORY ADDRESSES — AMALGAMATIONS—OBITUARY.

London, October 3, 1913.

Our Winter Session has begun. The traditional opening day—October 1—was duly observed at the Medical Schools; the Introductory Lectures have been delivered and sundry dinners duly honored. There are some notable changes in connection with the hospitals since last year; one of the most important is the removal of Kings College Hospital from town to a suburban district. It was expected this would have been completely carried out by the first but delay has been caused by a strike in the building trade. The Session was, however, formally opened on Wednesday. The new building is much larger than the old, contains 600 beds, and is equipped with every modern provision for hospital work. The removal is the more interesting an event as it is generally thought the ex-

ample will be followed by the Westminster and St. George's hospitals.

The Women's Medical School enjoyed a veritable triumph—nothing less than governmental recognition. Sir Charles Lukis had been announced to give the address. His subject was the "Medical Needs of India," and he took the opportunity of telling this greatly interested audience that he was authorized to state that the Indian Government had approved of a grant of £10,000 a year for a service of medical women under the Dufferin Association. He described in considerable detail the conditions of the scheme, but few of these needed notice, the great point being that it was at once to be put in force. At first 25 female doctors, from 25 to 30 years of age, will be engaged for service in India and Burma, to be retired at 48. Sir Charles expressed great pleasure that the scheme had materialized during his office of Director-General. He told the ladies that the civil surgeons were not the enemies they supposed and that he felt strongly that the bitter attacks made by them on their brethren were not at all deserved. He hoped men and women would work in complete harmony now that all irksome restrictions were being removed.

Charing Cross School, by its association with the London University and with King's College, has been enabled to make better accommodation for students, who now take preliminary subjects at King's.

The Public Health Department is greatly benefited and the laboratories can be more occupied with clinical research. Dr. William Hunter (the Dean) in his address said the students had increased in number since the new arrangement. They gained by the change by getting the best scientific education the University could give, while the School by freeing its energies and finance for the final, strictly hospital work, also gained. The principle of concentration between university and schools was sound and could be extended to other schools but the idea was not to include getting everything into one building.

At St. Thomas' Hospital a special department for tuberculosis under the control of a paid medical director has been arranged so as to form a part of the scheme for dealing with the disease as a matter of public health. There is a ward for diagnosis and the administration of tuberculin, also a bacteriological laboratory and the necessary equipment for the use of *x*-rays. A midwifery department to meet the requirements of the University is supplemented by a baby clinic for those born in the hospital, so enabling students to watch their progress from birth. It is to be hoped the physician in charge will appreciate his clinical opportunity and not suffer nurses to intrude on his functions and circulate old wives' fables in place of scientific study and instruction. Of course, the Children's Department remains as before in case of need after babyhood has passed, and there is a Lady Almoner's Department which is carried on toward all.

At University College a Department for Mental Diseases is being organized by Dr. Bernard Hart, thus filling a lacuna in the educational facilities. A more important development perhaps, may be considered the new special Department for Inoculation provided by the generosity of Sir H. Waechter. This will afford Drs. Thiele and Embleton the opportunity of carrying on those valuable researches on immunity with which you are no doubt familiar as they are important waymarks in the progress of bacteriological investigations. The department will be under the care of these scientists and will include an out-patient clinic.

The changes at Guy's Hospital School are, I am assured, now completed. They have been going on so long that one almost regarded them as permanent proceedings. Provison for research seems to be made in all departments. Close to the hospital the dispensary for tuberculosis will be utilized for teaching by the out-patient staff. Separate departments are also being arranged for children's diseases including orthopedics and infantile nutrition.

At the Middlesex Hospital changes are still going on; a new block is being built for pathology and hygiene, which it is hoped to complete by another year. At the opening the prizes were presented by Sir Squire Bancroft and the introductory lecture delivered by Mr. Sampson Handley, who set forth the importance of scientific teaching of medicine and lamented that present-day statesmen and politicians were most of them destitute of scientific equipment. He excepted, however, Mr. Balfour, who had shown keen interest in research, and Mr. Chamberlain, to whom the advances in tropical medicine owe so much.

At St. Mary's Hospital Sir Prescott Hewett presented the prizes and addressed the meeting on the work that had been done by the profession for the health of India where he was himself at one time a Lieutenant-Governor (Agra and Oudh). Wonderful results had been achieved as to epidemics, improved death rates, infant mortality, and general hygiene.

At St. George's Hospital Sir William Osler gave a scathing criticism of the examinational system which he was inclined to abolish, for it had gone to such excess as to consign a large proportion of students to the care of grinders and to no purpose. The spirit was taken out of instruction, teachers and taught went down together into Ezekiel's valley and stayed among dry bones. He would to a great extent substitute reports of work done, a plan which was in operation in Canada. He would replace the Chinese by the Greek spirit and enable the student to seek knowledge for itself, not for the end of passing examinations.

At the Westminster Hospital dinner last evening the approaching amalgamation with St. George's Hospital was mentioned, Dr. P. Stewart saying that a new institution would have to be built, the site of which was not yet fixed upon. Dr. de Havilland Hall spoke of two sites on offer and said the selection would be by a joint committee of the two hospitals. The medical officers of each of the uniting hospitals will take the same posts in the new institution and will, no doubt, find work enough. If the staff thus seems too large it will be easy to diminish it by not filling up vacancies for a time.

Recent deaths include Surgeon-Major David Woods, late A. M. S., in his eighty-fourth year. He was formerly surgeon in the artillery and on retiring from the army became medical officer to the W. W. District of London Post Office. At the early age of 48 another army medical officer, viz., Major George Johnstone Buchanan, died lately in consequence of a gunshot accident. He had passed over 17 years of his brief life in India, where he had seen active service, received honors, had charge of station hospitals, and been examiner in Indian languages. Dr. Tempest Anderson, consulting ophthalmic surgeon to York hospital and physician

to the Lunatic Asylum, retired from practice a few years ago in order to give himself entirely to scientific work. He was Hon. D.Sc. of Leeds, 1904. He wrote a volume on "Volcanic Studies," and was a fellow and president of several scientific societies.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

GERMAN SOCIETY FOR THE CONTROL OF VENEREAL DISEASES—SEXUAL DISEASES AND SOCIAL PROBLEMS—VENEREAL DISEASES AND INFANT MORTALITY—SEXUAL DISEASES IN RELATION TO MARRIAGE LAWS—THE TEACHING OF SEXUAL HYGIENE.

BERLIN, Sept. 15, 1913.

THE recent annual meeting of the German Society for the Control of Venereal Diseases was opened with a report of the progress made in the past year. One of the important events was the organization of a National Committee composed of physicians, jurists, government officials, and legislators. The exhibit dealing with sexual diseases, which exhibit formed a part of the Dresden Hygienic Exposition was utilized as a traveling exhibit, which was presented in various German cities. Provision was also made for the production in different parts of Germany of the drama by Brieux, entitled "The Shipwrecked."

"Sexual Diseases and Social Problems" was the title of a paper by Marcuse of Ebenhausen. He pointed out that the modern evolution of economic and social life gave rise to certain difficulties in the struggle for existence and in the maintenance of family life. Moreover, infant mortality and sexual diseases have a profound influence upon the race. Whereas on the one hand the limitation in the size of the family is accompanied by a diminution in infant mortality and hence by an improvement in the race, nevertheless, on the other hand, sexual diseases have a most pernicious influence upon racial hygiene. Preventive measures alone are effective in the campaign against these diseases.

The same theme was discussed by Blashko of Berlin, who perceives in venereal diseases one of the most potent causes of infant mortality. Since the cities contribute the largest number of cases of venereal disease, and since the cities continue to get larger and larger, the conclusion is reached that the influence of venereal diseases upon the birthrate is an increasing one. The attempt has been made to prohibit the use of prophylactics against venereal diseases, because some of these measures also serve to prevent conception. But it must be admitted that under certain circumstances the prevention of conception is justifiable. The increasing cost of living, particularly in the large cities, causes an unconscious restriction in the size of the family. When social and economic reforms succeed in stemming the tide of migration from the country into the city, then only will it be possible to predict the evolution of a healthier urban population.

Heller, a physician, of Berlin, and David, a jurist, of Breslau, discussed the subject of sexual diseases in relation to marriage laws. It was pointed out by the speakers as well as in the discussion that any change in existing laws is not necessary, inasmuch as present procedure is in most respects perfectly rational. Certain difficulties in judicial decisions will always arise in connection with sexual diseases. One must take account of a relative cure, in which the danger of contagion is minimized. Later non-contagious sequelæ may develop. Since besides there is no absolute guarantee for a perfect cure, and since the law can take into account only a standard of normal health, the legislator has given to the courts such a degree of latitude in applying the law that a miscarriage of justice is quite exceptional.

The teaching of sexual hygiene as a phase of the Society's activity for the future was a subject the discussion of which was opened by Chotzen of Breslau. The conclusion reached was that in spite of the difficulties in this sphere encountered by the Society and by school physicians, there was a growing need of instructing the youth in the principles of sexual hygiene. In a number of cities extension courses in this subject for teachers have been inaugurated. An important need is to awaken in parents a realization of the importance of this form of instruction.

Progress of Medical Science.

6. Medical Contribution of the State Board of Insanity of Massachusetts: Introductory Note. E. E. Southard.
7. Our Little Balloons. Some Observations on Gas and Ptosis. E. A. Codman.
8. Report of a Few Cases Where Sutures Instead of Packing Have Been Used After Submucous Resection of the Nasal Septum. M. L. Noyes.

5. X-Ray Study of Chronic Appendicitis.—A. W. George and I. Gerber state that in a series of cases which clinically show severe constipation, and more or less indefinite gastric symptoms, *x*-ray examination has shown the causes to be definite surgical conditions in the right lower quadrant. In all of these cases the demonstration of mere ileal stasis or obstruction is not as important as the more positive demonstration of the actual conditions. In chronic appendicitis the kinked and adherent appendix is shown. In case of Lane's kink one can demonstrate the fixed and distended terminal loop of ileum. In cases of Jackson's membrane one can show the effect of the adhesions under the fluoroscope, as well as the presence of a characteristic mechanism of filling. Various adhesions in this region as the result of old inflammatory disease or congenital anomaly can also be shown in the same manner. *Cecum mobile* and left-sided appendicitis can be readily demonstrated.

7. The Balloon Effect of Gas in the Hollow Viscera.—E. A. Codman discusses this subject. He states that the *x*-ray shows at least four little abdominal balloons which are constantly present in all individuals: (1) the stomach, (2) the hepatic flexure, (3) the splenic flexure, and (4) the small intestine. The last is a coiled compound balloon. The sigmoid and rectum might also be included and doubtless are the safety valves of the system since their gaseous content is more or less under one's voluntary control. First, the rectal balloon very nearly fills the bottom of the pelvis; over that the sigmoid fits quite naturally and almost fills the remainder of the pelvis. Now with much difficulty and crowding the distended small intestine is forced in under the transverse colon and the omentum nicely tucked down in front of it. The abdominal wall is then closed. The transverse mesocolon is

held up like a shelf by the compound balloons underneath it. On top of this shelf rests the stomach. It cannot drop down, and if the omentum is long and nicely tucked in it keeps the small intestine from bobbing up in front of the colon. With reference to ptosis the author states that many interesting questions come up, as follows: Should one not feed ptotic individuals with gas-producing foods, and teach them to endure temporary distress from distention for the sake of crowding their organs up into place? Should we not urge these individuals to retain the gas which they seem impelled to eruct or expel? What are the effects in the standing patient of inflation of the colon as seen by the *x*-ray? Do different articles of food produce different kinds of intestinal gas? Are different kinds of gas equally agreeable to the intestine? What are the toxic effects of the absorption of different gases? Why is it that some patients who are obviously not distended complain of distress from gas? What are the laws governing the manufacture and absorption of intestinal gas? Do individual coils rise and fall in the abdomen according to the weight of their contents?

New York Medical Journal.

October 11, 1913.

1. Differential Diagnosis of the Appendix by Aid of the Röntgen Ray A. J. Quimby.
2. Movements of the Two Halves of the Chest in Disease. L. Napoleon Boston and J. F. Ulman.
3. Tubercular Leprosy in a Negress. J. L. Kirby-Smith.
4. The Use of the X-ray in the Diagnosis of Diseases of the Chest and Abdomen. L. Glendening.

7. Physicians in English Literature. J. B. Neary.
8. The Value of Immunized Milk as a Prophylactic and Cure for Typhoid and Tuberculous Infection. J. Rosenberg.

1. **X-Ray Diagnosis of Appendicular Lesions.**—A. J. Quimby concludes that in chronic constipation due to delayed or inhibited peristalsis the appendix is usually diseased. In the differential diagnosis of diseases of the appendix the *x*-ray is essential. When the appendix is tied up in a mass of adhesions an accurate *x*-ray determination of the position of the appendix enables the operator to rapidly locate it at operation. Accurate determination of conditions present in appendicitis should be made before operation. When there are obscure symptoms in the abdomen which cannot be traced to a definite organ an *x*-ray examination of the appendix may show that it is adherent to some distant organ.

2. **Movements of the Two Halves of the Chest in Disease.**—L. Napoleon Boston and J. F. Ulman state that the facts obtained from the physical examination of the chest in a variety of pulmonary and cardiac diseases, abdominal disorders and cerebral lesions have for many years led Boston to believe that an accurate record of the movements of the two halves of the chest would furnish clinical data of special interest. The authors set about to determine chiefly (a) the difference in the amplitude of the curves of the pneumogram as produced by the respiratory movements of the two halves of the chest; and (b) delayed movements upon the side in which respiration was inhibited. A correlative study of the pneumograms of the two halves of the chest renders immediately apparent the fact that organic lesions of the lung and pleura, and both liquid and air in the pleural cavity, give unmistakable evidences through this method.

8. **Immunized Milk in Typhoid Fever and Tuberculosis.**—J. Rosenberg reports the results of his investigations as follows: Cows and goats can be immunized against tuberculosis and typhoid fever without any ill effects. During and after immunization the milk remains wholesome, differing in no respect from other milk. The milk of immunized animals contains antitoxins and bactericidal substances, differing in no respect from those of blood serum. The usual laboratory tests demonstrate the presence of agglutinins, precipitins, and bacteriolysins. Immunized milk is inimical and destructive to the microorganisms against which the animal is inoculated. Immunized milk lessens the liability of infection, owing to its bactericidal properties and producing passive immunity. It is useful and indicated in cases in which passive immunity is desired, and subcutaneous injections are impractical and contraindicated. Passive immunity and protection against infection are obtained by drinking the milk of immunized animals. The drinking of six ounces five alternate days produces protection against typhoid fever and tuberculosis. The milk must be taken on an empty stomach.

7. **Sterility in Women.**—E. Reynolds states that the normal secretion of the vagina may be altered by disease or there may be fermentative or other changes in the secretion given out by a normal mucous membrane. It is only by close observation of these secretions that the cause of the sterility in these cases can be discovered. A secretion of any one of the parts of the genital tract is most likely to be harmless to those above it, but an alteration of an upper secretion almost necessarily implies a similar abnormality of the secretions below into which it passes. Secretions in the patent vagina are rarely absolutely normal, but the importance of the condition must be estimated differently in the nulliparæ, who form most of the subjects of sterility, and in the multiparæ. A cause efficient against conception in the former may have no effect in the latter, owing to the slightly alkaline secretion of a lacerated cervix and the greater facility of the entrance of the spermatozoa. The most common causes of the alterations of the cervical secretion alone are retention and consequent thickening of the secretion behind a pinhole os. As regards the uterine secretion, which largely depends for its normality on the free drainage, so long as it is thickened, clouded, mucopurulent, or seropurulent, there will be no pregnancy. It is not generally realized that the Fallopian tubes have a secretion, but this must be inferred from their structure. Remembering that they are morphologically a part of the uterus it would seem it must be so. The author considers that besides a regular salpingitis there may be many minor conditions which affect the tubal secretion. The existence of ovarian infertility has long been accepted as possible. The alterations that are most common in sterility cases are slight to moderate enlargements caused either by the presence of numerous small to medium sized retention cysts, or of

unduly large, persistent, and frequently cystic corpora lutea. The claim that bilateral enlargement of the ovaries by retention cysts is a cause of sterility cannot at present be proven, but the importance of persistent corpora lutea is better established. The author has in his records cases of this kind and veterinary practice has recognized it in cows. As regards treatment the alterations of the vaginal secretion are apparently always due to infection, with the exception of profuseness, from general pelvic congestion or of those hyperacidoses from a general constitutional acidosis. Treatment naturally follows along the lines indicated by these etiologies. In alterations of the cervical secretions we should include the ordinary topical applications and perhaps curetting, but always the complete drainage of the cervical cavity. Any constriction should be done away with by operation if necessary. The only two methods of treating the uterine mucosa needing mention are curetting and disinfection and these are difficult to perform with thoroughness. Complete drainage by plastic work if necessary is essential and mere dilatation is inefficient. At the base of the whole subject lies the principle that even the ovarian infertilities are almost invariably associated with physiologically obstructive conditions, minor or major, and the patency of the genital canal is only that of its most obstructed point. This is not the mere mechanical patency, but that more complicated physiological patency allowing the conjugation of the germs and the subsequent growth which may be affected by such minute alterations that they escape diagnosis under merely routine observation.

10. **Calcaneus Paralyticus.**—J. P. Lord has demonstrated the value in this condition of the Whitman operation which he has performed twenty times in eighteen patients with most gratifying results. The technique is as follows: (1) The removal of the astragalus. (2) The freeing of the malleoli and the preparation of a new articulation. (3) The transplantation or resuture of the perinei tendons. (4) The backward displacement of the foot. (5) The fixation of the foot in equinus. A fixation plaster is kept on for four weeks, followed by an ambulatory plaster for five months. The results as given are: Correction of cavus and lateral instability, while the backward displacement checks dorsal flexion by direct contact and change in leverage, and the power of the transplanted muscles is made more effective. Most of author's patients recovered the use of their feet within three or four months. The typical or stereotyped technique is not to be absolutely adhered to since indications vary, especially when the operation is employed in conditions, as it can be, other than those for which it was originally devised.

12. **The Streptococcus in Chorea.**—G. F. Dick and T. Rothstein describe a streptococcus isolated from the throat of a patient who had had chorea for five years. Similar organisms have been isolated from more acute cases. It forms a heavy dirty white growth on blood-agar with a raised border and a wide zone of hemolysis. It grows aerobically and otherwise equally well on all ordinary media. It ferments milk with slight acid production but without clotting it. It does not ferment dextrose, lactose, mannite, inulin, or saccharose. On agar slants it is a Gram-positive organism occurring in irregular groups and short chains with an abundance of smaller Gram-negative forms, suggesting a mixed culture. In milk it grows in extremely long chains and staining shows no capsule. The intravenous injections of a dog with four agar slants produced choreic movements within twelve hours.

4. **Two Cases of Auricular Flutter.**—J. Hay states that he has had under observation for seven years a man aged 46 years in whom there has been demonstrated an auricular flutter with a 3 to 1 ratio and occasional irregular action of the heart. When first seen alteration of the radial pulse was pronounced; this disappeared entirely while the patient was under observation. Later a 4 to 1 ratio was observed. Then in 1908 under the influence of squill the auricular flutter changed to auricular fibrillation, which in its turn gave way to a normal sequence of contraction. The heart continues to contract normally, and the patient, much improved, is earning his living. The second case was that of a man aged 62, who came under observation with a large heart and peculiar arrhythmia. For 10 years the heart has been known to be increased in size, and occasionally irregular in its action. The auricular rate was 300; the ventricular 50 to 60, and coupled. A month later a 3 to 1 rhythm was present—auricular rate 261, ventricular rate 87. Cheyne-Stokes respiration and alteration of the pulse were noted. Large doses of digitalis produced a high grade of heart-block, but the auricular flutter persisted and is still present. The general condition of the patient is much improved. A small dose of digitalis daily is required to moderate the frequency of the ventricle.

5. **Hemiplegia Following Syphilis.**—M. Mackinnon points out that with regard to the etiology of syphilitic hemiplegia, it is well known that the vascular lesion, which is the commonest cause of this condition, is obliterating endarteritis, a condition which may be found in a number of smaller arteries throughout the body, but most frequently in the smaller terminal arteries of the brain. The pathological change affecting the vessel walls begins at a proliferation of the adventitia. The increase of newly formed fibrous tissue frequently tends to the formation of a thrombus in the contracted lumen of the vessel, and according as to whether the thrombus partially or completely obliterates the lumen of the terminal artery the result is a hemiparesis or a complete hemiplegia. There may be a condition of unilateral numbness and tingling during the stage of partial obliteration due to the ischemia of the part of the brain supplied by the obliterated vessel, and this condition may precede for several hours, or even days, the onset of sudden paralysis. This paralysis may readily be recovered from if the case is seen and diagnosed sufficiently early to allow of the appropriate antisyphilitic remedies being freely administered. Fortunately this is the result of treatment in most cases, but in a few the paralysis is permanent, on account of delay in treatment and the degeneration and softening of that part of the nervous system deprived of its blood supply. These vascular lesions are described as the early tertiary or late secondary manifestations of syphilis.

11. **Tuberculosis of the Uterus.**—J. W. Thomson notes that tuberculous disease of the uterus may be primary or secondary, usually the latter, the source of infection being a tuberculous salpingitis; but the infection may also be conveyed by metastasis through the blood stream, or directly by coitus, as pointed out by Montgomery. Tubercle bacilli have been found in the semen of phthisical patients. Those rare cases in which no other tuberculous focus is found constitute the primary form. Three varieties may be described—the corporeal, the cervical, and the combined or cervico-corporeal form. The corporeal is the most common form and may be miliary or ulcerative, and is strictly con-

fined to the body of the uterus, ending, it may be, abruptly at the internal os, as in Stewart's cases. The disease may present the features of an ordinary endometritis, the true nature being only revealed on microscopic examination, or it may involve the musculature of the uterus in varying degrees. The cervical canal may be blocked, resulting in a tuberculous pyometra—the so-called uterine phthisis. Montgomery reports a case in which the disease was confined to the myometrium and had originated there, and was probably transmitted by the blood-vessels. The cervical variety is rarer and may be of the miliary, ulcerative or papillary form, resembling the venereal wart or early carcinoma, but is less friable than the latter and has less tendency to bleed, and there is free muco-purulent discharge. There may exist tuberculous disease elsewhere, and the microscope would decide. The cervico-corporeal form is of extreme rarity.

5. Splenomegaly. Sir E. Sinclair Stevenson.
6. Report on Two Hundred Cases of Ringworm Treated by *X*-rays. F. Emrys-Jones.

4. Two Unusual Cases of Liver Abscess.—H. D. Rolleston reports these cases, both of which were fatal. One was that of a man aged twenty-five years in whom intrahepatic suppuration was the result of infection conveyed by means of an exploratory needle from an empyema. The other case was that of a latent hepatic abcess in an infant ten weeks old. Hepatic abscess is more often latent in children than in adults.

5. Splenomegaly.—Sir E. Sinclair Stevenson believes that until more is known about this condition, the patient's only chance lies in resection of the spleen. Osler has grouped under splenomegaly cases characterized by idiopathic enlargement of the spleen, with anemia. Whether this is secondary to the splenic condition or otherwise, or both, or secondary to some other cause, is not known. To a group of cases of enlarged spleen and cirrhosis of the liver accompanied by ascites the name of "Banti's disease" is given; this is, the author believes, the last phase of splenic anemia. The main symptoms are enlargement of the spleen and anemia of a secondary type but without leucocytosis, with, in most cases, various hemorrhages and a downward course. The spleen is greatly enlarged; in some cases this enlargement seems to have preceded the anemia; the lymphatic glands are not usually enlarged, the average of red blood corpuscles is below normal, the hemoglobin is relatively low, the leucocytes are diminished in number, but the differential count shows no special feature. There is often marked pigmentation of the skin, and as the disease advances so does asthenia. Rolleston has summarized the above symptoms as follows: Anemia of the type usually spoken of as chlorotic, namely, a diminution of red corpuscles with a diminished corpuscular value of hemoglobin; absence of leucocytosis, usually leucopenia, considerable splenic enlargement which cannot be correlated with any other known causes such as leucemia, tuberculosis, malaria, syphilis, and hepatic cirrhosis, the long duration of the disease, and the tendency to gastrointestinal hemorrhages. The diagnosis lies between splenic leucemia, Hodgkin's disease with enlarged spleen, hepatic cirrhosis (alcholic, syphilitic, or hypertrophic), and old cases of malaria with hypertrophy. When the spleen is removed in cases of splenomegaly the blood almost immediately improves in quality.

7. Bedbugs and Leprosy.—D. Thomson refers to the work of Sanders and Long who reported in 1911 that a considerable percentage of the bedbugs experimentally fed on lepers were found to contain the leprosy bacilli. Furthermore, a large percentage of the bedbugs caught within the dwelling of lepers contained acid-fast bacilli, presumably the bacilli of leprosy, while those caught in the dwellings of healthy people contained none. The presumption was that bedbugs might play an important part in the transmission of this disease. The author sought to verify these results. In the leper asylum at Palo-seco in Panama he fed 84 bedbugs on various cases of leprosy, acute and chronic, but was unable to find any trace of acid-fast bacilli in these insects afterwards. Seventeen bedbugs were caught in the beds of the patients at Palo-seco, and the author obtained eighteen more caught on the mattresses of the beds in the leper asylum at Trinidad. All of these likewise showed no trace of acid-fast bacilli. A total of 105 bugs fed on lepers and 35 caught in the beds of lepers, therefore, gave no evidence that these insects harbor or transmit the disease. A further total of 107 bedbugs were examined as controls; 21 of these were caught in dwellings in Liverpool, the remainder were caught in the Spanish wards in Ancon Hospital in Panama. The controls also gave negative results.

Symptomatology of Adhesive Pericarditis.—Tornai states that almost every case of this affection possesses an individuality as a result of which the adhesions differ in size, site, etc., with the patient. Thus in one subject there were firm adhesions opposite the left costal arch so that forced inspiration caused a funnel-shaped recess to form, while the cardiac pulsation was paradoxic. In all cases of supposed pericardial adhesions the author illuminates the thorax and causes the patient to assume a great variety of positions under forced inspiration. These maneuvers may bring out the existence of unsuspected adhesions. In many cases of adhesions deep inspirations cause sinking in of the end of the sternum. The author terms this depression the "inspiratory funnel breast." Pericarditic adhesions cause further symptoms. In one instance where after pericarditis and pleurisy the pericardium was widely adherent to the anterior chest wall, the apex beat was hardly perceptible by tranquil breathing. But upon forced inspiration the apex beat became very conspicuous, and at the acme the impulse was almost heaving. The liver is in almost every adhesive pericarditis somewhat enlarged. This, in the author's opinion, is in most cases due to inflammatory thickening of the hepatic capsule ("frosted" liver), with or without the secondary circulatory disturbances in the organ which arise therefrom. Tuberculous infection plays a notable rôle in the genesis of pericarditis. When edema results from adhesive pericarditis it is characteristic that in many cases not only the lower but also the upper half of the body is involved. It is possible that only the upper half becomes involved or is much more involved than the lower. The *x*-ray picture in adhesive pericarditis is always triangular, but in many cases we see projections, bands, etc., on one or the other margin of the heart shadow.

Medical Application of Diathermy.—Bergonié concludes his study of this subject as follows: Clinical results fully and completely corroborate physiological experiments. In all cases in which he has used the resource upon broken down, weak, and hypothermic subjects, the temperature, weight, arterial blood pressure, and strength have been elevated. He has further observed an improvement in the digestive functions and regular bowel evacuation. He has seen subjects in the greatest physiological nursery improve to such an extent under diathermy that in a few months they became equal to physical and intellectual activity, and remained thus when treatment was

discontinued. This admirable method, due originally to d'Arsonval has already come into extensive use. Diathermy acts upon temperature, circulation, and nutrition, and is readily mensurable. It will doubtless be of great benefit to the surgeon for sterilization of diseased tissues.

Münchener medizinische Wochenschrift.

September 30, 1913.

Icterus Neonatorum.—Ylppö, a Finnish physician who has done research work in the Berlin Institute for Combating Nursling Mortality (Queen Augusta Victoria House) has made an exhaustive study of all types of icterus neonatorum, including the physiology of biliary secretion in the fetus and newly born child. His conclusions are as follows: Icterus neonatorum is of purely hepatogenous origin; there is no hematogenous component. Children born with icterus show in comparison with the nonicteric no increased secretion of biliary coloring matter. Icterus neonatorum rests upon the fact that even for some time after birth the liver of the newly born allows a portion of its biliary coloring matter to go over into the blood, just as is the case with the fetal liver. Icterus neonatorum is therefore a physiological and simple phenomenon which at times may reach a pathological degree (icterus gravis neonatorum). In its course icterus neonatorum shows an autonomy which is not influenced by external causes like trauma and infection.

Functional Testing of Ovarian Activity.—Keller devotes much space to this subject, the data of which are so numerous and divergent that a summary can hardly be made to cover them. Cristofoletti's work, done about two years ago, allows us to believe that as a rule the ovary exerts an inhibitory action on the chromaffin system, and with extirpation of the genital glands the functional activity of the latter is increased. The chief phenomena of the menopause are such as would be produced by increased activity of the chromaffin system, as the result of abolition of the functions of the ovary. The author has worked along these lines, making use of adrenalin as equivalent to an increased activity of the chromaffin system. When small doses are given in cases of partial or complete abolition of ovarian activity the results are weak and inconstant. Hence the views of Cristofoletti and also of Adler to the effect that increased chromaffin activity is due to heightened sympathicotonus are only binding to a limited extent. Further research with atropin and pilocarpin in the same class of cases appears to show that we cannot as yet bring ovarian activity in necessary connection with heightened stimulation of the autonomous nervous system.

Diagnosis of Gastroenteric Affections with Aid of Abderhalden's Dialysis Procedure.—Kabanow of Moscow publishes a preliminary communication on this subject, the research having been made in the laboratory of Abderhalden. Besides the organs concerned, the work took cognizance of numerous diseases—achylia gastrica, chronic gastritis, acute gastritis, nervous hyperacidity, fermentative dyspnea, gastric, pyloric, and duodenal ulcer, etc. The method used agrees wholly with that pursued in the diagnosis of pregnancy, tumors, and psychoses. As in the foregoing conditions, the value of the test in comparison with others tends to vary at first, but enough evidence is obtained to show that with perfection of technique the site of the disease process can be located.

Deutsche medizinische Wochenschrift.

September 25, 1913.

Narcosis.—Traube first quotes the views of Verworn according to which narcosis represents a suffocative process exerted by the narcotics on the nervous central cells—in other words, they slow and inhibit the oxidative processes which take place within the cells. Hence, from this viewpoint narcotics are negative catalysators. The lipoid theory of Meyer and Overton has been seen to possess but a limited value in explaining narcosis. The author has studied in connection with the latter osmosis, surface tension, internal pressure, etc., in the hope of finding a physical or chemicophysical rationale based on active catalysis. Our organism is a catalytic machine, involving a constant play of catalysators. Paralysis of cell activity implies negative catalysis and stimulation active catalysis. Varying therewith is the surface tension of the cell water. Toxins lower the surface tension and inhibit oxidative processes. Yet when certain activities are slowed up others may be quickened; so that there is no absolute distinction between the two types of catalysators. It is known that a great number of drugs and poisons have power to vary the surface tension which variations in turn are responsible for the behavior of the cell activities.

Treatment of Pregnancy Toxicoses.—Engel relates an instructive case: Patient 23, iii-para. Last menses middle of April. One month later was taken with chills, fever, vomiting, diarrhea, anorexia, pains. She was too weak to sit up and at times showed marked meteorism. After three weeks in bed she began to improve but quickly resumed the lying posture. Fever persistent, high. Medical opinion varied much. Phantom pregnancy was suspected; also pyosalpinx. The existence of these was disproved. When examined by author patient should have been five months pregnant. Patient had become of a typhoid habit. In addition to pregnancy a cyst, probably ovarian, was palpable—perhaps the center of an infection. Laparotomy confirmed in part the diagnosis as a dermoid of the ovary was found. The urine was found albuminous, meteorism so great as to interfere greatly with respiration. Life being threatened vaginal cesarean section was performed, and after slow, uneven recovery patient once more became normal. The strangeness of the case lay in the complete absence of lesions such as ordinarily would cause such symptoms. There was neither peritonitis nor ruptured pyosalpinx. The dermoid, a closed tumor, was not infected. Uterus was normal. The urinary disturbance was technically an acute hemorrhagic nephritis, which, however, cleared up after delivery. The prolonged fever subsided under the same conditions. We have therefore to impute all these symptoms to the fetus itself and declare the case a hitherto undescribed form of pregnancy toxicosis, the latter, however, typical in one sense (supervision after conception, persistence until delivery, attended by a "pregnancy kidney," complete rebelliousness to treatment, incidence of gastric irritability and vomiting, etc.)

Congenital Deficiency of the Cranial Vault.—F. Langmead reports the case of a boy, aged 4 years, in whom at the posterior part of the interparietal suture a small pulsating area, the size of a dime, could be seen and felt. In this position there was a small depression admitting the top of the little finger. At the bottom of the depression a small hole existed which apparently transmitted cerebral pulsations. The up-and-down movement of the scalp was noticed by the mother.—*Proceedings of the Royal Society of Medicine.*

The Frequency of Breast Feeding.—M. Thiemich calls attention to the fact that Rietschel has recently shown that in the suckling of firstborn infants during the first six to eight weeks of life a definite number of feedings is not requisite. Some of the children thrive with five feedings, others require more, sometimes as many as eight feedings in the 24 hours. The author finds that in healthy infants it is never necessary to exceed five or six feedings in the 24 hours, provided that each time both breasts are fully emptied.—*Monatsschrift für Kinderheilkunde.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SELF SELECTION (*Continued*).

Self Selection by Those Applying for Low-priced Insurance.—Experience, generally speaking, teaches that the selection among applicants for the cheap forms of policies is adverse to the interests of the companies, and that the mortality varies inversely with the premium. On the other hand, the dictum by the eminent actuary, Mr. McClintock, that "you cannot get a high mortality on high premium insurance" emphasizes a part played by what may be called legitimate self selection among those applying for a higher grade of insurance with gratifying results as it conserves the interests of the mass of policy holders. The exercise of adverse election among certain applicants for low-priced policies is the result of the natural tendency of human nature to make the best possible bargain, and some men, yielding to this impulse, will present their interests in the most favorable light or even practice deliberate fraud by concealing or misrepresenting important facts affecting them as risks. Applicants of this character probably experience some inward admonition of trouble which cannot be detected by a medical examiner but which may be known to members of their families as well as themselves, and this may be the first motive of their presenting themselves for insurance with the hope that the doctor will not discover any physical weakness. In a few of these cases the dishonesty may be of an unconscious form, the result of a perverted mental process.

A typical illustration of the mortality rates when the exercise of self selection is not interfered with, appears in the following figures taken from an article by Hunter (Transactions of the Actuarial Society of America, Vol. 7), in which the British Offices experience, 1863-1893, in regard to different forms of policies, is compared and brought up to the American standard.

RATIO OF ACTUAL TO EXPECTED DEATHS

Plan	Insurance Years	
	1–5	All Years Combined
Term	131%	123%
Ordinary Life, Participating	98%	110%
Limited Payment Life	71%	76%
Endowment	70%	81%

The results of adverse selection are indicated in the table by the high mortality under term insurance, the experience in the first five years being especially bad. It is a mortality which may be looked for among the class of people applying for term insurance, unless precautionary measures are observed. The mortality under the ordinary life policies is also sufficiently high to call for improvement. The low mortality among those carrying limited payment and endowment policies signifies in a general way that those taking them were fully justified in entertaining a high degree of confidence that they would live past the date of maturity of the contracts. The fact that endowment policies do not show better results than the limited payment is due largely to the custom which prevails in many companies of offering endowment insurance to applicants who are not first class lives and who have applied for cheaper forms, and the endowment class, in this way, has a burden thrust upon it. If the inferior risks were excluded, the mortality in the endowment class would undoubtedly be as low, if not lower, than that under the limited payment life. As it is, the limited payment class is made up chiefly of applicants who believe in themselves, wish to finish the premium payments as soon as possible, and then live to old age free from demands for further payments.

The classic arrangement shown in the accompanying table would have to undergo considerable modification if the statistics of entrants of more recent years were studied. It is inserted chiefly with the object of exhibiting the adverse effects following the exercise of self selection before the sufficient restraining force of an improved medical selection came into existence. The technique and requirements of medical examinations have advanced and scientific discrimination has greatly modified and improved the practice of medical selection. Some companies have adopted a more stringent selection than others, so that the experiences are bound to differ; but the mortality among holders of the cheaper class of policies, on the whole, has become lighter through a closer scrutiny of the risks and the elimination of undesirables, and it is not uncommon now to find the death rate under term insurance as low as among those carrying the higher grade policies. This favorable turn in the mortality ratio does not signify by any means, however, that the element of self selection is less potent than in former years. Self selection is always at work and will be to the end of time. The more favorable conditions experienced at the present time, bringing the mortality more approximately to a normal point, if not entirely so, are due to improved methods of medical selection. They cannot be accounted for by changes in the death rate among the general population, as the advantage from the lower mortality now found in the younger ages is practically lost by the companies through the increasing rate among those in the advanced ages.

The Standardization of the Medical Blank.—The variation in the size of blank and the introduction of matter foreign to the medical examination to conform to the finished policy, make it impossible to have a blank that is uniform in size or general appearance, but Dr. H. B. Miller, Medical Director, Security Mutual Life Insurance Company, Lincoln, Neb., considers that a standard line of questions would benefit both the examiner and the company. Many of the variations are useless. A report should be so worded as to place the responsibility of the examination entirely upon the examiner and he should be held by all companies as responsible for incompetence or neglect in filling out blanks. The examiner's reports are intended to give the medical director a thorough mental view of the applicant, and accurate examinations are necessary, not only on this account, but also to give proper protection to the company and each and every policyholder. The reports should cover all the ground necessary to put each applicant in the class where he belongs. Many of these reports, Dr. Miller thinks, contain matter that might be properly considered a part of the business contract rather than a subject requiring the particular attention of the medical director.—Medical Section, American Life Convention, Hot Springs, February 26-28, 1913.

Book Reviews.

Preventive Medicine and Hygiene. By Milton J. Rosenau, Professor of Preventive Medicine and Hygiene, Harvard; formerly Director of the Hygienic Laboratory, U. S. Public Health Service. With chapters upon Sewage and Garbage, by George C. Whipple, Professor of Sanitary Engineering, Harvard; Vital Statistics, by Cressy L. Wilbur, Chief Statistician, Bureau of the Census, Department of Commerce and Labor; The Prevention of Mental Diseases, by Thomas W. Salmon, Director of Special Studies, National Committee for Mental Hygiene, etc. Price $6. New York and London: D. Appleton & Company, 1913.

It is impossible in this place to enumerate the large number of topics that come within the scope of this work, which has been written by one who has had practical experience as a quarantine officer, as a laboratory investigator, and as a student of the broader problems of preventive medicine, and who has been eminently qualified to write this book. The words "preventive medicine" have such a familiar and even commonplace sound that at first thought one would say that they imply merely the enforcement of well-known sanitary regulations, and the observance of a few important rules of personal hygiene. But criteria in preventive medicine have greatly changed within the past few years. Themes and practices of less than half a decade ago have been greatly modified or entirely abandoned. Thus terminal disinfection after measles has been given up as a public sanitary measure in New York City. The belief in aerial infection is now almost obsolete. On these and numerous other questions the author presents the most advanced views. He deals with the subject of preventive medicine from two viewpoints: from that of individual, and from that of his environment. The work is divided into twelve sections, as follows: Prevention of the communicable diseases; immunity, heredity, and eugenics; foods; air; soil; water; sewage disposal; refuse disposal; vital statistics; industrial hygiene and diseases of occupation; schools and disinfection. The entire work consists of 1,074 pages, and is fully illustrated. The author writes in a style that is at once clear and elegant. There can be no doubt that this work will rank high as a standard, and will be of service to both public health officers and private practitioners.

School Hygiene. By Fletcher B. Dresslar, Ph.D., Specialist in School Hygiene and School Sanitation, United States Bureau of Education. Price $1.25. New York: The Macmillan Company, 1913.

The vast scope and importance of this volume may be readily gleaned by a perusal of its table of contents. The chapter headings are as follows: The meaning of hygiene and its relation to education; play and playgrounds; location and construction of school buildings; lighting of schoolhouses; school desks; school baths; convenient and sanitary water supply for school buildings; drinking cups and drinking fountains; toilets for schools; the need of pure air; ventilation; open-air schools; heating of schoolrooms; humidity in the schoolroom; eye defects and school conditions; the hearing of school children; the teeth of school children; stuttering; fatigue; hygiene of instruction; the care of exceptional children; medical inspection of school children; hygiene of school utensils and books; cleaning schoolroom; qualifications and duties of a school janitor; and disinfectants. This table of contents reminds one of the program of the recent Congress on Educational Hygiene. The author approaches his subject with sympathetic interest and expert knowledge. He is strictly up-to-date in his advocacy of the vacuum method of cleaning schoolrooms. One important chapter is that which deals with the hygiene of instruction. It is interesting to note that some states of our country and Switzerland have enacted laws which forbid the assignment of home study for all children below the high-school period. A list of selected references is appended to each chapter. The author has admirably acquitted his task in writing this volume, which should be in the hands of every school teacher in the land.

The Career of Dr. Weaver. By Mrs. Henry Backus. Illustrated by William Van Dresser. Price $1.25 net. Boston: L. C. Page & Company, 1913.

Dr. Weaver is a brilliant young laryngologist with money-making and social aspirations, who in the flush of his professional success forgets some of the ideals that should accentuate the conscientious practitioner. Contrasted with him is his brother, "Dr. Jim," who is content to be the assistant, but whose ideals are still untarnished. About them both there is entwined a narrative of love, of politics, and of intrigue. The story is an interesting one, and has been written chiefly with the view of holding a mirror up to some of the evils of modern medical practice. With the insight of one who has studied the profession at close range, the author discourses on fee-splitting; on medical advertising by means of reprints; on dispensary evils; on the proprietary hospital, etc. She speaks of the man who failed to succeed because "he lacked magnetism, or self-assurance, or a certain professional address which is half the battle." The trend of popular instruction in hygiene is not ignored, and the abomination of flies, the menace of typhoid fever, the controversy over benzoate of soda, and the question of a national health department all find a niche in the "medical" novel. It is quite natural as with all lay writers who write on medical topics that the author should make a few errors, partly of exaggeration and partly of fact. Her student is studying laryngology in the first year of his medical course. She speaks of "some bacteriological slides of a virulent tumor." But on the whole the author evidently has a broad knowledge of medicine and of its votaries. She writes in a charming literary style, and although much of her story consists of time-worn platitudes concerning a certain class of practitioners, her story is an interesting one and will repay reading.

Diseases of the Rectum and Pelvic Colon. By Martin L. Bodkin, M.D., New York, Rectal Surgeon, St. Mary's Hospital, the Williamsburg Hospital, and the Howard Orphan Asylum; Late Rectal Surgeon, Bushwick Hospital. Illustrations specially drawn by Francis A. Deck. Price $3.50. New York: E. B. Treat & Company, 1913.

In this handy volume of 416 pages the author has attempted to present a complete and simplified exposition of the diseases of the rectum and pelvic colon, with reference to the relation between these diseases and disorders of the body as a whole, and particularly of the upper digestive tract. The author displays a mastery of his subject and understands the needs of the general practitioner who he believes should be able to diagnose any rectal disorder, and in many instances to administer the appropriate treatment. The book is handsomely illustrated with a large number of original drawings. A new theory is advanced as to the causation of hemorrhoids. These are regarded as secondary to catarrhal proctitis resulting from digestive disturbances. The inflammation of the rectal mucosa causes a gradual hypertrophy and the sliding down of a small portion of the mucous membrane, which then constitutes a small hemorrhoid. This is soon filled with a serous exudate. It is not likely that this view of the origin of hemorrhoids will supplant the older and well-seasoned theory. In general this book is well written. But the text contains a large number of errors. Thus on page 256 occurs the following: "Cold water enema are sometimes more satisfactory than drugs." On the same page one notes the misprint, "Ung. stramonni." The description of pruritus ani is not satisfactory. The modern views advanced by the late Sir Frederick Wallis and by the late James P. Tuttle as to the important influence in the production of pruritus ani, which is exerted by inflammation of the submucous crypts leading from the sinuses of Morgagni, are not mentioned. The author correctly shows the important relation between pruritus ani and constitutional and digestive disorders. He also points out that an imperceptible moisture resulting from a mild proctitis may be an important factor in the production of pruritus. The chief merit of this volume is its originality. The author has the courage to ignore some of the established teachings. He has tried to write a work that is practical, and that is intended to be a real aid to the general practitioner.

Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung. (Mit Ausschluss der Tuberkulose.) Herausgegeben von Prof. Dr. L. Brauer, ärztlichem Direktor des Allgemeinen Krankenhauses Hamburg-Eppendorf: Redaktion: für die Originale: Dr. H. Schottmüller (klinischer und bakteriologische Teil) und Dr. H. Much (Immunitätswissenschaftlicher Teil); für die Ergebnisse: Prof. Dr. H. Lüdke, in Würzburg. I Band, 3 Heft. Price 6 marks. Würzburg: Curt Kabitzsch, 1913.

This constitutes the third and concluding number of the new and valuable periodical on the infectious diseases and immunity studies. It contains the following articles: "The Infectious Aspect of Criminal Abortion," by Lindemann; "Researches on the Course of Antibody Production," by Lüdke and Körber; "The Serum Therapy of Serpiginous Corneal Ulcer—A Review," by Gebb; "The Influence of Anaphylaxis Studies on Dermatology and Venerology," by Bruck, and "On Colisepsis," by Fejes.

Stammering and Cognate Defects of Speech. By C. S. Bluemel. Volume I. The Psychology of Stammering. Volume II. Contemporaneous Systems of Treating Stammering: Their Possibilities and Limitations. Price $5 net. New York: G. E. Steckert & Company, 1913.

The author approaches this subject from the psychological side. He presents an original theory of the origin of stammering. This theory appeals to the reader because of its simplicity and because of its agreement with established psychological data. According to this theory a person stammers because of a transient auditory-amnesia. The failure of the auditory image occurs not in the case of the consonant, but in the case of the succeeding vowel. The stammerer really has no difficulty with the consonants, he hesitates in speech, repeats the initial consonants of certain words, interpolates an aspirate sound between the consonant and the vowel, or hesitates after sounding the consonant, because he cannot bring up at the moment the auditory image of the vowel. This is the essence of the author's theory. There is thus an objective similarity between stammering and aphasia. Pure stammering is due to auditory amnesia and is uncomplicated by extraneous symptoms. Secondary manifestations may arise, such as facial contortions, which may be due to the physical effort to overcome the stammering. Autosuggestion may accentuate the difficulty. Mental confusion and fear may be added as complicating factors. The author shows the relative importance of these secondary manifestations. He discusses the various theories that have been advanced by others to explain stammering. Some followers of the Freudman school actually seek a sexual basis for it. Stekel says that "originally it is the fear of betraying some secret during speech." The author presents a lucid exposition of the method of treatment. The sufferer must first overcome the secondary manifestations, such as multiple thought, fear, and inhibitive autosuggestion. He then has to contend with the auditory amnesia. This may be partly overcome by various methods of training. An acoustic sensation can awaken the refractory auditory image. Hence the stammerer should commence the articulation of the word. This also eliminates multiple thought and vacillation of the will which both complicate the difficulty. The second volume of this work deals with the various current methods of treating stammering. These methods are classified into groups according to the emphasis placed upon some physical defect that is supposed to lie at the basis of stammering, as faulty respiration, faulty vocalization and vowel production, and faulty articulation. The author also discusses verbal exercises, mechanical appliances, psychological methods and "stammering schools" and "speech-specialists." A glossary of terms and a bibliography conclude the work. There can be no doubt that this represents a scholarly and eminently valuable contribution to both psychological and medical literature.

Aids to the Diagnosis and Treatment of Diseases of Children. By John McCaw, M.D., R.U.I., L.R.C.P. Edin., Senior Physician to the Belfast Hospital for Sick Children; Clinical Teacher of Diseases of Children, Queen's University, Belfast; ex-President, Ulster Medical Society; Author of "Aids to Infant Feeding and Hygiene." Fourth Edition. Price $1.25 net. New York: William Wood & Company, 1913.

It is unusual to find as in this small volume such a comprehensive treatment of the subject-matter. It reminds one of the thin-paper pocket editions of the classical authors. In its 431 pages of text the entire subject of pediatrics is presented with satisfying fullness of detail and comment. The following new matter finds a place in the present edition: epidemic cerebrospinal fever, mental deficiency, cerebral diplegia, the myopathies, night terrors, and status lymphaticus. The rest of the text has been carefully revised. The treatment of disease of children is accorded considerable attention. Many authorities are quoted and the latest literature is freely cited. There can be no hesitation in recommending this book to the student and even to the practitioner as a valuable guide.

Thérapeutique Clinique des Maladies de l'Estomac et des Symptomes Associés. Par L. Pron. Price 6 francs. Paris Libraire: Maloine, 1913.

The principle guiding the author in writing this volume is to emphasize the fact that chemical problems play but a small part in the treatment of diseases of the stomach, and that motility and above all sensibility dominate the symptomatology. The important rôle of the nervous system in the evolution of gastric disease is also fully recognized. The volume is a most valuable guide containing many practical suggestions and formulæ.

The Diseases of Children. By Henry Enos Tuley, M.D., late Professor of Obstetrics, University of Louisville, Medical Department; Visiting Physician Masonic Widows' and Orphans' Home, Louisville, Ky.; Secretary of the Mississippi Valley Medical Association, etc. With 106 engravings and three colored plates. Second Revised Edition. Price $5.50. St. Louis: C. V. Mosby Company, 1913.

This is a well-written presentation of the subject of pediatrics for the use of students and practitioners. The section on infant feeding is particularly complete and accurate. In the appendix there are given a large number of alternative methods of infant feeding, as recommended by Holt, Chapin, Kerley, and others. The methods and standards for the production and distribution of certified milk are given in full. These should prove a valuable guide in communities where the organization of a Milk Commission is being contemplated. The illustrations are good and the colored plates are particularly true to life. The book may be recommended as a safe and practical guide to the student and practitioner.

The Changing Girl. A Little Book for the Girl of Ten to Fifteen. By Caroline Wormeley Latimer, M.D., M.A., former Instructor in Biology, Goucher College. With a foreword by Edward Bok, Editor of the *Ladies' Home Journal*. New York: Fleming H. Revell Company, 1913.

The author shows a profound and sympathetic knowledge of her subject. The physiological and psychological transformations of the girl at puberty are described in clear and elegant language which the average parent will have no difficulty in understanding. It is questionable whether this book is suitable for the girl of ten or even of twelve. Think of the little girl of ten poring over a sentence like this: "From time immemorial girls have been taught to suppress and conceal every vestige of emotion connected with sex, not only from the world at large, but from themselves, and the result of all these years of repression has been to create a state of things in which sex instinct in women shows itself only in indirect ways!" Here is the Freudian psychology served up as a pabulum for the young. The book may, however, be recommended to the mother as a safe guide by which she may instruct her growing daughter in matters pertaining to a most delicate subject, which cannot be suitably dealt with in schools and in books for children.

Stories of Doctors, for Doctors, by a Doctor. By W. T. Bertrand, M.D. Price $1.00. Boston: The Roxburgh Publishing Company, 1913.

This book narrates the experiences of a group of seven physicians who went into the backwoods to spend their vacation together. One catches a glimpse of the trials of the country practitioner in the unwelcome tasks which the recuperating practitioners were compelled to perform in ministering to the natives who got wind of their whereabouts. The interchange of yarns forms an interesting feature of this adventure, and many of the stories told are new and interesting.

Diseases of the Eye. A Handbook of Ophthalmic Practice for Students and Practitioners. By G. E. de Schweinitz, A.M., M.D., Professor of Ophthalmology in the University of Pennsylvania and Ophthalmic Surgeon to the University Hospital; Consulting Ophthalmic Surgeon to the Philadelphia Polyclinic; Ophthalmic Surgeon to the Philadelphia Hospital; Ophthalmologist to the Orthopedic Hospital and Infirmary for Nervous Diseases. With 360 illustrations and 7 chromo-lithographic plates. Seventh Edition, Thoroughly Revised. Price $5.00 net. Philadelphia and London: W. B. Saunders Company, 1913.

The popularity of a treatise on any subject in medicine is a fair indication of its fitness for the purpose for which it is designed. Judging from this standard, if from no other, de Schweinitz's work on the eye, which now appears in the seventh edition, is excellently adapted to the uses of students of ophthalmology. The present edition has been carefully revised and now presents the results of the latest authoritative studies in this branch of medicine. The newer aids in examination, as the Schiötz tonometer and the diaphanoscope; the more recently described diseases, as dystrophia, epithelialis cornæ, and massive exudative retinitis; the newer operations, as Elliot's trephining operation for glaucoma, Toti's operation for dacryocystitis, etc., are described in the present edition. The volume is a worthy product of its renowned author. It is one of the best of modern textbooks on the eye and fully deserves the popular endorsement that it has received.

Society Reports.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting Held October 2, 1913.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Otology.

Concomitant Association of Otitis with Other Diseases.—Dr. FELIX COHN presented this paper, in which he first considered the various conditions under which concomitancy occurred. Otitis might be a part of a general infection, or it might be a specific part of a general infection and in concomitant relation with another specific focus. The otitis might be proximally associated with extension of inflammation in the vicinity, the inflammation occurring synchronously and not as a sequela of the otitis. The otitis might be entirely independent of the associated disease, the associated disease being either acute or chronic in character. The otitis might be the pathway through which the infection traveled producing various conditions not direct complications of the otitis, and finally the otitis might occur in the course of various diseases, chronic or acute, the relation not directly dependent upon the incumbent disease. The diagnosis of concomitancy from the standpoint of the aurist must be taken into consideration in every case where a disproportion occurred between existing symptoms and the results of the otoscopic examination, where symptoms became manifest or conditions arose which could not be referred to the otitis or to complications of the otitis. With a negative otoscopic examination showing only a moderate degree of inflammation, a sudden or gradual rise of temperature might be sufficient to create a strong probability of a complicating fatal meningitis in a case of apparently simple otitis. The author stated that the reason otitis was found associated as a part of a general infection, or as a specific part of a general infection, was based upon the pathological fact that inflammation of the middle ear was an early manifestation in almost all infectious diseases. This early otitis differed from secondary invasions in infectious diseases in that while the otitis might be catarrhal, serous, or even seropurulent, its course was usually benign. With the exception of pneumonia and cerebrospinal meningitis and these infectious forms due to a specific organism, the occurrence of otitis appeared to be due to a hematogenous, toxic, or specific infection in contradistinction to the latter forms of otitis in which the inflammation might be caused by secondary invasions of those organisms which were usually present in genuine acute otitis media. As to the frequency of these early forms of otitis Nadolescing reports its occurrence four times in one hundred cases of measles, in two cases three days, in the third five days, and in the fourth nineteen days before the eruptive stage. Braun recorded eight cases of early otitis in pneumonia in which the severe middle-ear inflammation appeared as the cause of the unusually high temperatures which were eventually found to be due to the pneumonic infiltrations. A review of the epidemics of cerebrospinal meningitis in recent years had demonstrated that concomitant otitis media was a comparatively frequent association of this disease. The importance of a bacteriological examination of the aural contents in purulent forms of otitis and early lumbar puncture for the early recognition of this association was evident. Occasionally tenderness about the region of the mastoid and even further back toward the emissary vein, simulating ostetitis, was found concomitant in the early stages of pneumonia and typhoid fever. Such cases were occasionally first referred to the aurist until further developments established the diagnosis. In regard to the third group of cases, the speaker said that the proximal association of otitis was so closely allied to the complicating forms of otitis that it needed but passing mention as the aural inflammation was of secondary importance. However, the existence of primary ostetitis, primary subdural abscess, primary brain abscess, and serous and purulent forms of meningitis might be worthy of mention. Cases of otitis followed by meningitis were much more frequent both in children and in older individuals than was generally assumed and the importance of being on the lookout in apparently simple cases of otitis should always be borne in mind. In considering those cases in which the otitis was entirely independent of the associated disease the author cited a number of cases including instances of the association of otitis and polioencephalitis, otitis and hysteria, otitis and malaria, otitis and syphilis, otitis and tuberculosis, and otitis and the toxemia of pregnancy, and also a case of chronic otorrhea and streptococcus meningitis, in which it had to be assumed that the meningitis was induced by the tonsillitis and a concomitant exacerbation of the chronic otorrhea and that the middle ear was the pathway of the meningeal infection. In discussing more in detail the association of otitis and meningitis, Dr. Cohn stated that cases of acute otitis with meningitis due to other organisms besides the meningococcus presented a clinical picture like that of fibrinopurulent meningitis in which, as in the epidemic form, the meningitis was apparently primary and accompanied by an acute otitis of varying intensity. These cases gave such a distinct picture that it seemed proper to segregate them from cases of otitic meningitis. In otitic meningitis the infection was transmitted by extension of suppuration through preformed channels from the middle ear, or through the labyrinth by contact with diseased bone, or through intermediate circumscribed lesions. The extension of the inflammation to the brain occurred at all stages of the disease, the lapse of time before the onset of the meningitis depending on the intensity and location of the primary affection. The clinical course of this form of meningitis presented a striking similarity in all the cases coming under the author's observation and resembled that form of meningitis which had been described as the creeping form consisting of two stages, a latent stage with uncertain prodromata, and a terminal stage with all the symptoms fully developed, as found in the final stage of every purulent meningitis. The classical symptoms usually associated with the initial stage of meningitis were entirely absent in all the cases. Until the onset of the terminal stage, the temperatures were uniformly low and the pulse rate in proportion to the temperature. There were two symptoms which were apparently pathognomonic, the difference between the rising temperature and the otoscopic findings, and the rising temperature and diminishing pulse rate. The writer then considered briefly otitis associated with intestinal disturbances in infants, with the later stages of pneumonia, with empyema of the chest in children, and finally its association with endocarditis, leucemic conditions, nephritis, etc. The otitis associated with these diseases differed from the protopathic type in that it was always perforative. While otitis of the ordinary type might often lead to the severer aural complications, the otitis of this form, with the exception of the hemorrhagic type, ran, according to his observation, an almost invariably benign course. In searching for the etiology of this class of cases one had to consider such contributory factors as embolic conditions, a degeneration of the epithelial cells of the mucous membrane producing a diminished resistance to microbic infection, minute hemorrhages in the mucous membrane of the middle ear, and possibly in some cases especially localized selection of metastatic invasions through blood or lymph channels. The otitis occurring in the later stages of pneumonia with empyema of the chest in children was characteristic of this form of otitis The otitis associated with endocarditis, leucomia, nephritis, severe forms of icterus, etc., in the final stages of these diseases presented similar characteristics. The purulent discharges might dry up and the otitis resolve a number of days before the fatal issue. The association of otitis with gastrointestinal disturbances in infants had been made the subject of special study by Ponfick and Preysing. The former held the view that the gastrointestinal condition was caused by the direct absorption of toxins from the middle ear, or by the mechanical ingestion of pus through the Eustachian tube; the latter, on the other hand held that the intestinal disturbance was the primary condition and the otitis was caused by the general debility, although admitting that the views of Ponfick could not be easily cast aside and that in some cases the otitis might be the primary condition. The prognosis of this form of otitis was naturally entirely dependent upon the associated disease.

Dr. ISAAC ADLER said that the mass of clinical material that was presented was of the greatest value to all, not alone the otologist but the general practitioner as well. Although he felt somewhat timid in speaking before such an audience, with some hesitancy he said he wished to mention one point that Dr. Cohn had not brought before them, a form of otitis which all met with so frequently and he believed few of them knew sufficiently about. It occurred concomitantly associated with rheumatism. This was a form of otitis, fortunately a harmless one, which as a rule preceded rheumatic affections. There was the usual exudate in the middle ear, but so far as his experience went it was not purulent but serous. It was absorbable. There was found a peculiar sensitiveness about the mastoid and even some swelling. Dr. Adler said he knew of a number of cases in which this rheumatic otitis

had been taken for an ordinary suppurative mastoiditis and operated upon. He recalled one case in which both mastoids were opened but not to the advantage of the patient. Therefore, he believed that this was a form of otitis which was well worth studying. It occurred before the general rheumatic affection as a rule. There were cases in which the rheumatism disappeared first, the otitis remaining and for a long time. Conditions were present which might be termed rheumatic osteitis. Antirheumatic medication did the most good in these cases.

Dr. W. Sohier Bryant said that the concomitance of otitis with other diseases was so usual that it might be compared with the concomitance of fire and smoke. This general concomitance of otitis with other diseases was due to the physiological location of the ear and to its anatomical connections. Whatever inflammatory diseases affected the digestive or respiratory tracts, must, of necessity, cause corresponding changes in the ear. Pharyngitis or pneumonia, tonsillitis or typhoid fever had their bearing on the ear and betrayed themselves by a catarrhal otitis media, a purulent otitis media, otitis externa, or an auditory neuritis. The reverse of this proposition was also true, that was, that otitis caused diseases of the respiratory and digestive tracts. The ear being located between the nasopharyngeal and the cranial cavities diseases of these regions easily reached the ear by extension. Obviously the ear was brought into relation with other diseases through the blood and lymph streams, through the multitude of nerves with which the ear was connected, and by juxtaposition with other organs. Diseases of organs situated near the ear caused otitis by direct extension or aspiration, for example, the adenitis of lymphatic and salivary glands, erysipelatous dermatitis of the face, sinusitis of the nose, pharyngitis tonsillitis caused otitis by direct extension of the inflammation to the ear. The blood vessels and lymphatics carried bacteria and toxic substances from diseased organs to the ear causing otitis. Otitis might occur through diseases of the auditory and of the facial nerves and through diseases of the tympanic plexus of nerves, autonomic and sympathetic nerves comprising the geniculate, Gasserian, ciliary, splenopalatine, otic, petrus, and submaxillary ganglia, and the ganglia of the root, together with the third, fourth, fifth, seventh, eighth, ninth, and tenth cranial nerves and the second and third cervical nerves. All general pathological states and diseases could produce inflammatory changes in the ear. The reverse was equally true and obvious. By direct extension through the neck, head, and throat, and by aspiration, otitis produced meningitis, brain abscess, venous thrombosis, pharyngeal abscess, cervical cellulitis, mediastinal cellulitis, lymphadenitis, erysipelatous pharyngitis, gastric and duodenal ulcer, appendicitis, and bronchopneumonia. Through the blood and lymph vessels otitis produced diseases by thrombosis and emboli to the brain and system generally. Otitis also produced pneumonia, pleurisy, sinusitis, metastatic abscesses, nephritis, bacteriemia, and toxemia, and many other diseases and conditions. Otitis caused nerve reflex disturbances, such as cough, epilepsy, neurasthenia, myasthenia, defective equilibration, psychoses, and psychasthenias. Otitis affected the general system through toxic products and metastases, causing inflammations. It also affected the system through nervous exhaustion, which in turn produced abnormal secretions of the ductless glands, thyroid, pancreas, pituitary, suprarenal, and others. Dr. Bryant recommended the following as good advice: "Keep your eye on the ear in diseases of other organs and your eye on other organs in diseases of the ear." The specialist on the ear should be keen to discover any defects in other organs and should have these defects rectified for the benefit of the ear, while specialists in other lines should be prompt to discover and mitigate any damage to the ear.

Dr. William M. Polk called attention to the concomitant association of otitis with influenza; a few years ago this was looked upon as of so small importance as not to command any attention whatsoever, even from instructors in otology.

Dr. Cohn in reply, said that rheumatism was one of the diseases that should have been mentioned as a concomitant association with otitis; this was a form of protopathic type and in association with general infections. In answer to Dr. Bryant he said he only intended to call attention not to *how* otitis arose but the *association* of otitis with other diseases. He only referred to the forms which were concomitant or associated, and not the genuine forms of otitis. This was a subject that had interested many otologists in an experimental way. For a long time it was believed that the pneumococcus was found in many forms. They tried to determine whether otitis was of hematogenous origin, whether due to a general infection, etc. In his paper Dr. Cohn really tried to confine himself to the concomitant association of otitis with other diseases, and not to the various forms of otitis as occurred in various diseases.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 10, 1913.

Dr. Henry Dwight Chapin in the Chair.

Hydrocephalus Treated by Cisterna-Sinus Drainage.—Dr. Irving S. Haynes reported the case of a child thirteen months of age, who was operated upon February 8 for hydrocephalus. The condition was typical. The cisterna-sinus drainage was employed. The technique of this operation was described before the Surgical Society in January, and was published in detail in the *Annals of Surgery* for April. The aim was to direct the cerebrospinal fluid from the arachnoid spaces into the sinus, thus imitating the normal course of the fluid. The operation consisted in exposing the base of the occipital bone, and uncovering the confluence of the sinuses and the cisterna magna. The fit was good, there being no leakage of blood and no fluid. Dr. Haynes presented the patient and called attention to the new bone formed at the edges of the gutter in the occipital bone. *X*-ray photos showed the cannula. The post-operative changes were interesting. The temperature steadily rose to 106°. The pulse was uncountable; the respirations were 42. Colonic irrigations were employed and the temperature gradually came down to 100.4° on February 10, and from then on there was an uneventful convalescence. The circumference of the head had diminished 1⅛ inches. The change in the patient's general condition was quite satisfactory. With regard to the general subject of drainage, the cerebrospinal fluid had been drained into almost every conceivable locality, under the skin, the fascia, the muscles, into the subperitoneal tissues, the peritoneum, the chest, and from one part of the cerebrospinal space to another, but without permanent success. This cisterna-sinus operation was an attempt to conduct the fluid into the blood stream where it went normally. It remained to be seen whether the flow could be maintained. Dr. Haynes believed that if the drainage was continuous until the child reached the age of three years Nature would take up the work by the Pacchionian bodies and perfect the cure.

Dr. Marshall Carleton Pease, Jr., said that since the operation there had been a distinct lessening in the spasticity. He looked upon the results obtained by Dr. Haynes as quite remarkable.

Dr. Charles Herrman said that he had seen the patient presented by Dr. Haynes at the Vanderbilt Clinic before the child was taken to the Post-Graduate Hospital and that in addition to the change in the size of the head there had been some improvement, although the improvement was not very great. The child had had hydrocephalus for many months. The condition had come to a standstill. After lasting for so many months one could not expect to obtain much benefit from any surgical procedures. One could remove a certain amount of fluid but the damage to the brain was such that one could not to any great extent improve the child's condition. The child's mentality was practically the same as before the operation. There was no question but that the size of the child's head had been diminished, but he doubted whether there would be much improvement in other respects. In a certain number of cases of hydrocephalus lumbar puncture would do some good. In the patient presented the conditions were not favorable for any marked improvement because of changes which had already taken place in the nervous system.

Dr. Irving S. Haynes, in closing the discussion, said that all recognized the fact that a proposition of this kind was experimental. Surgery alone offered a chance for patients afflicted with hydrocephalus, but it had failed in the past. Perhaps in the case presented the patient would have gotten well without surgical interference, but there was no reason for such an expectation. All that he claimed for his work was the following: First, there had been a distinct diminution in the size of the head. Secondly, there had been a marked diminution in the intracranial pressure. Thirdly, the child's entire attitude had changed. Fourthly, his spasticity was less. It was interesting to note that when he was constipated, his spasticity increased. Hearing seemed to be normal, for the child turned his head when spoken to. The child's intelligence or mentality had apparently been bettered; he remained comparatively quiet and did not whine and cry, as before. With regard to lumbar puncture, the results in these cases were negative except in the nine cases reported by Bókay.

Simple Syringe Transfusion with Special Cannulas. A New Method Applicable to Infants and Adults. Preliminary Report.—Dr. EDWARD LINDEMAN presented two sets of cannulas, two tourniquets, and twelve syringes. Two sets of cannulas were employed, one for the donor and one for the recipient. There were three cannulas to each set, and each telescoped within the other. After describing the operation in detail he offered the following rules and comments: 1. Bright polished surfaces of syringes and cannulas were requisite. 2. A syringe used once should not again be employed until thoroughly cleaned with sterile water. 3. Air must be avoided; this, however, offered no difficulty. 4. The tourniquet of the patient must be removed after the vein was entered with the cannula. 5. The tourniquet remained on the donor throughout the operation; a momentary release of the tourniquet might be advisable once or twice during the course. 6. Dexterity and speed were requisites for success. 7. Syringes could be evacuated more rapidly than they could be filled without any harmful effects; this difference in time allowed for the attachment of syringe with warm saline solution every now and then, thus preventing clotting. Both arms of the donor might be used simultaneously. The same vein could be used repeatedly for subsequent transfusions, since no thrombosis or permanent injury to the vessel occurred.

Radiographic Studies of the Chest in Tuberculous Meningitis.—Dr. I. O. WOODRUFF presented this communication which was based on the observation of fifteen cases of tuberculous meningitis in the children's wards of Bellevue Hospital. He said that the idea of making a routine examination of chests suggestive of tuberculous meningitis occurred to him while studying the plates taken in a number of cases of suspected early pulmonary tuberculosis. It seemed probable that tuberculous meningitis might give a series of cases ideal for this purpose as a fair proportion would likely go to the necropsy table. A study of the autopsy records showed that there existed in the chest all stages of tuberculous infection from, rarely, the mere involvement of the lymph nodes to a general miliary infiltration of both lungs. It could be ascertained whether the *x*-ray could be relied upon to diagnose early tuberculous infection of the bronchial glands and early infiltration of the lungs, and also to what extent in those cases showing pulmonary involvement the interpretation of the radiographic shadows corresponded with the pathological lesions present. Since autopsy records showed a pulmonary involvement beyond incipiency in 88 per cent. of the cases, it seemed that a routine radiographic examination of the chest, in hospital work at least, might prove to be of real value in diagnosis, especially in those cases in which the absence of a skin reaction and the inability to demonstrate the tubercle bacilli in the spinal fluid left the diagnosis open to question. A study of 285 cases of tuberculous meningitis covering a period of eight years yielded only twenty-six autopsies, 88 per cent. of which showed considerable pulmonary tuberculosis. The von Pirquet test and examination of the spinal fluid were both negative in the same child in five, or 33 per cent., of the fifteen cases which formed the basis of this report. The report from the radiographic findings showed no tuberculosis in one case; tuberculous glands and some involvement of the right lower lobe in two cases; more or less extensive involvement of one or both lungs in twelve cases, or 80 per cent., a figure approaching rather closely to the necropsy findings just cited. In four of these twelve cases the von Pirquet and spinal fluid tests were negative. There were six post-mortem records, two of which were of the cases showing slight pulmonary and bronchial gland involvement; the other four were of cases in which radiographic reports of more or less extensive pulmonary involvement were rendered. In the first group comprising two cases the radiographic report of the first case showed an area of infiltration of the right root involving also the right lower lobe; there were also shadows suggesting enlarged glands. At post mortem slight congestion was found at the bases of the lungs which were crepitant throughout. The bronchi contained a slight amount of mucopurulent material but no tuberculosis. The glands were not enlarged and not tuberculous. In this case the lower cervical glands were enlarged and caseous. In the second case the radiographic report showed very distinct markings, probably a tuberculous bronchopneumonia in the right lower lobe. At post mortem the lungs and lymph nodes were negative and showed no tuberculosis. In the second group the radiographs showed marked lesions. These cases all showed extensive pulmonary involvement post mortem The plates were very instructive and interesting. The study of all the cases suggested that the interpretation of the radiographic shadows in the chest in children and infants, when there was considerable tuberculous involvement of the lungs, could be relied upon to diagnose the nature of the pathological process at least. As there was usually considerable pulmonary involvement in tuberculous meningitis, this measure might be of distinct aid in the diagnosis of this disease, especially in those cases in which the disease was not absolutely certain owing to the failure to find the tubercle bacilli in the spinal fluid and where the corroborative evidence of the von Pirquet test was lacking. It seems likely that the *x*-ray could not be a deciding factor regarding the presence of an early tuberculous involvement of the chest where on clinical grounds there was uncertainty as to the existence of tuberculosis, nor could the *x*-ray be relied upon even in more advanced cases to furnish accurate evidence of the exact pathological lesion present. These conclusions were merely suggestive as the paper was but a preliminary report and they were of little value until supported by much more extensive observation.

The Prognosis of Tuberculosis in Infancy and an Account of a Ward Epidemic.—Dr. ALFRED F. HESS read this paper and made the following summary: Tubercle bacilli were not necessarily fatal to young infants, as they had some resistance to these organisms even when they were less than six months of age. As the result of observing a large group of infants, all of whom were less than two years of age, and some less than six months, the speaker concluded that latent tuberculosis might exist in earliest infancy, and that the prognosis was not always fatal. He had been able to follow these infants four to five years and found them in most cases well. However, clinically, tuberculosis in infants was fatal when involving the internal organs. Dr. Hess also reported on the infection of a ward of ten infants who were placed in contact with a tuberculous nurse for six weeks. Seven of these infants gave negative tests before the nurse took charge, and a positive von Pirquet reaction soon after she was removed from the ward. The infants did not leave the precincts of the asylum, and were not subjected to tuberculous infection in any other way.

Heliotherapy as Seen in Rollier's Clinic.—Dr. I. S. HIRSCH read this paper. He said that Leysin, situated in the southwestern part of Switzerland at an elevation of 4,000 feet, had the exceptional climatic conditions of intense sunlight, dry atmosphere, freedom from dust and insects, but little wind, moderate warmth in summer, and not too intense cold in winter, thus making possible uninterrupted life in the open air. Here Dr. Rollier, in 1903, inaugurated the first clinic for the exclusive treatment of surgical tuberculosis by sunlight. He was so successful that three clinics were built, accommodating 300 patients. The charges ranged from 7 to 10 francs a day. The buildings faced south and were protected from the winds of the north and east by the hill upon which they were built. The hospitals were constructed with spacious balconies so that all the beds might be wheeled out through the wide windows. All the patients' rooms faced south. By means of large folding doors the wards could be completely exposed not only to the south, but to the east and west. On sunless days and at night the airing was continued in this way. The treatment consisted first of the general exposure of the entire naked body and, second, of the localized exposure of the particular site of the disease to the sunlight without any intervening lenses or glass. When the days were cloudy a simple exposure of light and air was carried out, but the patients were partly clothed. Individuality was the watchword of the treatment based on the general principles stated. When the patient had accommodated himself to the new environment exposure was commenced, beginning with the feet and gradually extending upward until the chest was reached. These parts were exposed a few minutes every other day, then several times a day. It was only when the entire body was pigmented that a general exposure was given. For the success of the treatment it was absolutely essential that no dermatitis should occur. The eyes were protected from the direct light of the sun. The length of the period of exposure was gradually increased from two to four hours once or twice a day, then to four or five hours once or twice daily. Even when the maximum exposure was given there were two hours during the day when the patient was removed from the sunlight. Under this exposure the skin turned to a very dark brown, and an early advent of this pigmentation was considered a sign prognostic of good results. Blondes did not respond nor did they bear the sunshine as well as brunettes and they required longer treatment. The exposure to the sun caused

a hypertrophy of the skin itself, increasing its vitality and resistance, and protected the organism against extremes of temperature. Such conditions as acne and furunculosis were never seen in patients thus exposed. In winter, when there was at least 1 meter of snow on the ground, and sometimes two, these children lay naked on the balconies and those well enough to walk wandered about naked in the sunlit snow. The radiation from the snow was so intense that the temperature in the sunlight was 50° to 60° C., while at the same moment it might be 0° in the shade. After general pigmentation had been obtained the rays were applied locally to the site of the disease. At first only about five minutes per day, then two or three times a day, then from ten to fifteen minutes, and, finally for a period of two to six hours. The joint was usually immobilized by means of counterweight extension. When immobilization was effected by means of a plaster jacket, an opening was cut in the jacket in front and back to permit the exposure of the affected part to the sun. The first local effect of the sun's rays was an analgesic one, which was produced with remarkable rapidity and quickly permitted of the removal of the fixation apparatus. In the treatment of caries of the spine, the patient received half the sunlight treatment on his back over the kyphosis and half on the abdomen for the treatment of the abscess. When suppuration with sinus formation was present, sinuses were not treated antiseptically or surgically, but exposed directly to the sunlight. Sequestra were extruded without any surgical assistance and the fungus granulations were absorbed. One was impressed at Leysin by the excellent health of all who were exposed to the sunlight and by the rapidity with which the local and general condition of the patients improved. The demonstration of the results, as controlled by photograph and radiograph, was convincing even to the most skeptical. All forms of peripheral tuberculosis were treated in this way, and also peritonitis, cystitis, adenitis, and all forms of intestinal tuberculosis. Rollier applied this treatment to the sternum and ribs in cases which were practically inoperable from a surgical standpoint, but which might be cured by this method after a year's treatment. The most wonderful result of all was the reformation of a joint after almost complete destruction and ankylosis. Rollier's results spoke for themselves; about 00 per cent. of the cases were cured. In one and one-half years, out of 60 cases of tuberculous joints, 54 were healed, five improved, and one died. Of 60 cases of tuberculosis of the bone, 54 were healed, five improved, and one died. Of 45 cases of tuberculous peritonitis, 32 were healed, five improved and one remained stationary, while four died. Of 88 cases of tuberculous lymph nodes, 81 were cured, six improved, and one died. The effects were undoubtedly due to the application of the sun's rays and all other factors were but adjuvants. Under the general effects of the sun's rays might be considered the vasomotor exciting effect on the skin reacting on the internal circulation and resulting in increased metabolism. The pigmentation and hypertrophy affected the condition of the red blood corpuscles, raised the hemoglobin index, and increased the number of cells themselves. The local effects were the well known bactericidal effects of the sunlight on the tubercle bacilli, pus cocci, etc., and the infra-red and ultra-violet rays had undoubtedly chemical and heat effects. It was to the ultra-violet rays that Rollier attributed the great part of the results achieved. He allowing nothing to intervene between the exposed surface and the sunlight on the physical principle that the thinnest sheet of glass would completely absorb the violet rays. On stormy days the wounds were treated by either *x*-rays or Cooper-Hewitt light, both containing ultra-violet rays.

Tuberculosis Acquired Through Circumcision.—Dr. L. EMMETT HOLT presented this paper. He said that tuberculosis by direct wound inoculation, while not frequent, occurred often enough to demonstrate that it was a real danger. Willy Meyer, in 1887, collected a number of such instances and added the report of a case of his own in which tuberculosis was acquired through ritual circumcision. Since that time only two cases had been reported in this country to his knowledge, one by Ware, and one by Sara Welt-Kakels. He was of the opinion that many cases occurred which never found their way into the literature. The case to be reported was of more than ordinary interest because of the virulence of the infection and the early death of the patient, in fact, death occurred at an earlier age than in any instance on record so far as the writer knew. The patient, a baby three months of age, was admitted to the Babies' Hospital on February 24, 1913, with an extensive ulceration of the penis. The parents were healthy, as were the other living children. Four children had died of acute diseases. The baby was reported to have weighed eleven pounds at birth and had been breast fed up to the time of admission to the hospital. When eight days old ritual circumcision had been performed, the blood having been sucked in the usual manner. At the end of a week suppuration was observed and ulceration followed, which had gradually extended up to the time that the patient entered the hospital. Glandular swellings were noticed in the groin about two weeks after the operation; these swellings had increased in size, although they showed no tendency to suppuration. The digestion had been good and the nutrition well preserved until three weeks before admission, since which time there had been a steady loss in weight, refusal of food, slight fever, and cough. There was a discharge from one ear and from the nose. A few days previous to admission there had been a scanty maculovesicular eruption over the trunk and extremities. At the time of admission the child did not appear acutely ill. He weighed eleven and one-half pounds. Scattered over the body were fifteen or twenty lesions resembling those of varicella. These lesions were three to four millimeters in diameter, vesicular at the periphery, and crusted at the center. A very narrow zone of redness surrounded them. Many râles were present over both lungs but there were no signs of consolidation. The heart was normal, spleen and liver much enlarged, and the abdomen much distended. There was a chain of nodular swellings on both sides in the inguinal region. The penis showed complete destruction of the skin by ulceration quite up to the abdominal margin and to the base of the scrotum. The tuberculin test gave a strong positive reaction and tubercle bacilli were found in the discharge from the penis, in the sputum, and in the scrapings from the cutaneous lesions. The bacilli from the ulcers of the penis were carefully differentiated from the smegma bacilli. The child lived sixteen days after admission, during which time there was a constant temperature of 99° to 101° F., going sometimes as high as 102° to 103°. There were progressive weakness, increasing cough, and râles through the chest. There were no cerebral symptoms. Just before death the leucocytes and polymorphonuclears were greatly increased. The cerebrospinal fluid taken two days before death showed a faint globulin reaction and an excess of cells. The skin lesions dried up slightly, but no new ones appeared. The autopsy showed tubercles in practically every organ of the body, except the stomach and duodenum. Examination of the heart showed a small yellow tubercle upon the coronary artery, a tuberculous nodule in the wall of the right ventricle, and a smaller one in the right auricle near the entrance of the superior vena cava. This involved the pericardium, endocardium, and cardiac muscle, and was cheesy. The mesenteric lymph nodes were greatly enlarged and caseous; extending upward from these were a chain of large caseous retroperitoneal lymph nodes which followed the iliac arteries. One of the iliac arteries contained a cheesy lymph node in its adventitia. The tuberculous character of this lesion was confirmed by microscopical examination. Both middle ears contained pus. The man who performed the circumcision was examined and, though no physical signs of disease were found in his chest, he was pale and emaciated, and looked decidedly tuberculous. From his sputum two acid-fast bacilli were found which looked like tubercle bacilli. Thus the evidence of infection through circumcision seemed conclusive. The lesions found at autopsy pointed strongly to a spread of the infection through the lymphatic system beginning from the wound and afterward a general blood infection. The lesion in the iliac artery and the tuberculides of the skin were particularly worthy of note. It was Dr. Holt's belief, he stated, that the latter lesion was often overlooked. He had seen this lesion in two other cases during the present season. Dr. Holt said that he had collected reports of thirty-nine other cases which, with this one, made forty cases of tuberculous infection through circumcision. Of these forty patients, sixteen were known to have died, seven were reported to have made partial recoveries or were scrofulous, in twelve the final results were not given, while only five were said to have recovered. The youngest fatal case was the one just reported. The usual cause of death had been general tuberculosis. In a number of the reports several children were said to have been infected by the same operator. As a rule the symptoms and progress of the disease were similar to the case reported. In a very considerable number of the cases it was reported that the glands broke down and abscesses formed, usually in from two to three

months from the time of the initial infection. The cases in which suppuration of the inguinal glands took place and which were operated upon were among those in which the results were best. The symptoms of widespread general infection rarely occurred earlier than the third or fourth month. That the infection spread through the lymphatic system seemed certain and early removal of the inguinal glands would therefore appear to be the most important measure to be employed in checking the spread of the disease. To be successful this, of course, must be done early. The first diagnosis made in a large proportion of the cases was syphilis; much time had consequently been lost in the administration of antisyphilitic treatment. The writer expressed the belief that syphilis was much less frequently acquired in this way than tuberculosis and that the latter disease should be first suspected. While the number of cases acquired through circumcision was considerable there must be a much larger number which never found their way into the literature. These facts led the writer to emphasize the statement of the late Professor Maas, that "it is the duty of the physician to raise his protest against ritualistic circumcision in every case."

Dr. William P. Northrup reported the case of a child; one of a series of five. In all of these children there was what might be called a delicate constitution. The child he reported had a high temperature and a tentative diagnosis of pneumonia was made. Physical signs showed scattered râles—they were, in fact, quite universal, appearing in all parts of the lungs. There were many dry subcrepitant râles, but no sign of consolidation.

Dr. Sara Welt-Kakels reported the case of a boy six months of age. His parents were perfectly well. The child's history was good. There was no syphilis or tuberculosis in the family. On the ninth day after birth the child was ritually circumcised. From that time on, according to the mother, the child never appeared well and suffered from fever and gastric disturbances. When the child was four weeks old the inguinal glands became enlarged and some ointment was prescribed. At the Mt. Sinai Dispensary Dr. Welt-Kakels saw the child some seven or eight weeks later and she detected fluctuation and aspirated the gland contents, getting a serous fluid mixed with flocculent material. Tubercle bacilli were found in the pus. A few weeks later the glands were removed. The von Pirquet reaction was positive. The man who circumcised the child ritually was said to be suffering from a chronic cough and had since died; the little boy recovered.

Stated Meeting, Held May 13, 1913.

Dr. Henry Dwight Chapin, in the Chair.

Tracheal Obstruction Due to the Thymus Gland.—D. Henry Lowndes Lynah reported this case. He said that the patient was a child, 3½ years of age, who was admitted to Willard Parker Hospital on August 16, 1912, suffering with laryngeal diphtheria for which he had been intubated by the ambulance surgeon before admission. The pharynx was congested and there was a moderate amount of exudate over the tonsils and uvula. Cultures from the same showed the presence of diphtheria. The hear action was accelerated but the muscular tone was good. There was a peculiar tactile fremitus over the anterior aspect of the chest and an area of dulness in the interscapular region posteriorly and extending downward for about two inches. There were also scattered moist rales, and many transmitted sounds through the chest, as was the rule in intubated patients. The abdomen was prominent. The temperature was 101° F., pulse 150, and respirations 32. A dose of 10,000 units of antitoxin was administered. Three days after admission the temperature went up to 103.4°, pulse to 160, and respirations 60. There was an area of consolidation over the right lower lobe posteriorly. The intubation tube was removed on August 22, but it was found necessary to reinsert it after thirty minutes owing to a spasm of the adductors. The tube was removed permanently on September 10 though the physical signs in the chest remained unchanged. There was slight evening rise in the temperature at this time but the von Pirquet reaction was negative. Five days after the extubation there was slight stridor and the lungs showed areas of bronchial breathing over both lower lobes posteriorly, with many rude rhonchi over the anterior lateral aspect of the right lung. The dullness shaded off to flatness over this area and an exploratory puncture was made but no fluid was obtained. The child was discharged at the request of his parents but under protest on September 21, but was readmitted on November 2, suffering with a violent spasm. He was reintubated and given an injection of antitoxin. There was no anaphylactic shock. The tube remained for a week when it was removed and the patient was discharged at the end of three weeks. In January he was again admitted to the hospital, and Dr. Lynah said that after hearing his history he concluded that the recurrence of the dyspnea was due to subglottic hypertrophic laryngitis. In making the examination of the larynx, the applicator passed through the larynx but met with an obstruction in the trachea, the child becoming cyanotic. After the applicator was removed the patient coughed up a quantity of mucopus which showed no tubercle bacilli but staphylococci in abundance. The chest signs were the same as those previously recorded, and it seemed probable that there was a bronchiectatic cavity at this site. The child had been asthmatic since birth and at times became very cyanotic and would break out in a cold clammy sweat. Thymic asthma was now suspected. He felt convinced that he was dealing with a case of enlarged thymus gland with pressure symptoms. This diagnosis was confirmed by the x-ray plates. The mother refused operative interference or even reintubation. Thus far all that had been done was to give urotropin internally which seemed at first to improve the mixed infection in the bronchi, and later mixed staphylococcus vaccine was given. He proposed doing a Veau operation if the mother should at any time give her consent. So far there had been 50 cases reported with a mortality of 33 1/3 per cent., and many of these died several days after operation. The interesting points in this case were that the dyspnea was relieved by intubation, but returned shortly after the removal of the tube, and that the patient being of the type associated with status lymphaticus could receive two injections of antitoxic sera without any anaphylaxis and with only a slight erythema following the administration of the first dose. It was a question whether the case was one of laryngeal diphtheria or of tonsillar diphtheria with thymus involvement.

A Case of Bilateral Empyema Thoracis Treated by Successive Rib Resections.—Dr. Abraham Zingher reported this case, which he stated occurred in a child 6½ years of age, who gave a negative family and past history. He was taken suddenly ill on November 8, 1912, with bronchopneumonia. The disease ran a severe course with high temperature, marked prostration and rapid emaciation. He saw the patient in consultation on November 29, when the general condition was poor and the temperature was running a septic course, but no signs of fluid were present in the chest. Both lungs showed the presence of numerous crepitant and subsrepitant rales, with an associated patch of impaired reasonance. He saw the patient again on December 13, when he found some doubtful signs of fluid in the left chest and the aspirating needle showed the presence of pus. A part of the eighth rib was resected the same night and tubes were inserted for drainage. Some improvement followed during the next two weeks, but on January 7, 1913, flatness was detected in the right chest and operation showed the presence of pus on this side also. On January 8, 1913, intercostal incision was performed on the right side and tubes inserted for drainage, but as the discharge, at first profuse, soon became scanty and imperfect, a secondary resection was done on February 1. After this the patient made an uneventful recovery and was discharged from observation on April 1st. A light ether anesthesia was employed in all the operations. On opening the right chest the patient went into shock but was quickly revived by active stimulation. The pneumococcus was found in the pus on both sides. The general course of these cases was like this one and the majority of those found in the literature, that was, that of a bilateral bronchopneumonia, complicated by a one-sided empyema. In cases of double empyema the interval operation was always performed when possible. When pus was found on both sides simultaneously the question of opening both sides of the chest at the same time came up; the danger of course was that of a double pneumothorax. According to Hallin, who, in 1905, collected 114 cases in the literature, this danger was exaggerated. He enumerated several cases where both sides had been operated upon simultaneously with good results. If one decided to wait, most authorities were agreed that it was better to operate upon the left side first so as to relieve the pressure on the heart and to avoid the danger of a complicating pericarditis. The pus from the right side could be aspirated and then after several days the chest could be opened. Shock occurred occasionally, either at first or at the time of the second operation; when it occurred it should be treated by active stimulation.

Vulvovaginitis in Young Children.—Dr. Nathaniel

Barnett presented this paper. He declared that the frequency of this affection among children and the unsatisfactory treatment given them in most dispensaries had led the authorities of Mount Sinai Hospital to establish a special clinic for the treatment of this disease. He had had charged of this clinic and this paper was the result of his observations during the past year. Vulvovaginitis was exceedingly prevalent in hospitals and in schools where children used a common toilet. The homes of the poor were also favorable to the spread of the disease. Dr. Barnett said that he had found very little in the literature to help him in his work, and that the material which he had studied consisted of fifty cases. In the management of this clinic two nurses were always present, one to help him in his work and one to attend to the social welfare work. The methods of examination suggested by Dr. Koplik in 1893 were, in the main, adopted. The Skene urethral speculum was utilized to inspect the vagina and cervix together with the aid of a head mirror. Spreads of the secretion were taken before the various therapeutic procedures were instituted. Attendance at the clinic was three times weekly, and nurses visited the homes and urged delinquent ones to attend regularly. In spite of these efforts only 26 of the patients continued treatment.

As to the etiology of the affection it was found that most of the patients had contracted the disease in hospitals or other institutions or from sleeping with mothers or sisters who had vaginal discharges. In the larger number of cases, however, the origin could not be discovered. The disease was of varying duration, some of the cases giving a history of recent origin, while in others it had lasted for years. The chronicity and resistance to treatment of the affection was characteristic. As to the seat of the disease, in most cases a small amount of dried pus was found on the labia and pus was seen coming from the vagina, but the external appearance of the hymen might be normal in a pronounced gonorrheal process. The vagina was dull pink with pus in the folds of the rugæ throughout its entire length and occasionally hemorrhagic spots were seen in the walls of the canal. In the cervix they found marked changes; it was in all cases deeply congested and pus was seen exuding from the cervical canal. The posterior fornix contained a certain amount of pus which bathed the cervix continually. The present series of cases presented the following complications: arthritis, twice; chronic general peritonitis, once; pelvic peritonitis, twice; and painful heel once. The *x*-ray picture in this case showed a periosteal exostosis. In addition to the method of treatment employed in the past as irrigations, instillations, local applications, vaccines and illumination of the vagina with a speculum and treatment of the parts locally, the author had applied the electric endoscope, which in his opinion was a distinct advance in the management and treatment of these cases. For the irrigations they had used potassium permanganate 1-1,000, or bichloride of mercury 1-4,000, or Lugol's solution of iodine 1-500. The alcoholic solution of pure iodine could not be used without great pain and discomfort. For instillations the solutions used were nitrate of silver one-fourth per cent. and argyrol 10 per cent. The applications were introduced with a cotton applicator and the vaginal wall swabbed. Fourteen cases were treated with vaccines; injections of from 100,000,000 to 500,000,000 dead bacteria were given at intervals of from three to seven days. All of the above mentioned methods of treatment had received a painstaking trial, and he had come to employ the following method of treatment: The mother was instructed in preparing and giving the permanganate douche and this was given at home daily. The patient was put on urotropin daily. In the clinic the patient was treated with the electric endoscope. In giving this treatment the Kelly endoscope was employed, being inserted as far as possible. The obturator of the endoscope was withdrawn, the light inserted and with no other manipulation than withdrawing the tube one-quarter to one-half an inch, the cervix presented at the distal end of the tube. Any secretion was then removed with the applicator, and iodine (Lugol's solution) was applied directly to the cervix and the vaginal walls as the endoscope was slowly withdrawn. These endoscopic treatments were carried out three times a week. With the use of any of these methods of treatment the discharge soon stopped, but this of itself did not constitute a cure, for smears remained positive for months after all visible signs of the discharge ceased. Two negative smears at intervals of two weeks might be followed by positive ones. The smears taken from the posterior fornix might be positive while at the same time those taken from the hymen might be negative. None of his cases treated with vaccines showed any improvement so far as the discharge was concerned. Those complicated by arthritis and treated by vaccines improved rapidly and a complete cure followed the use of the vaccines. The case with the painful heel was improved by the vaccine treatment but there was a recurrence of severe pain at intervals. The case were considered cured if smears taken weekly were negative for three weeks in succession. At the end of six months only seven cases could have been said to have been cured by irrigations alone. Seven of these cases in which irrigations had failed to effect a cure were treated with the endoscope, and five were cured within a month. Five additional cases that had failed to improve under the irrigations were now being treated with the endoscope and were improving rapidly. The first important factor to bear in mind was the infection of the cervix and the difficulty of reaching this nidus of infection by the ordinary methods of treatment. Irrigation of the vagina was neither practical nor of great value as the affected parts were not reached directly and the treatment had to be continued too long. Cures could be effected by the treatment of the cervix as he had indicated in a short period of time and strong solutions could be applied to the cervix and vaginal walls directly without causing pain. Prophylactic measures, such as sleeping alone, separate clothing, the wearing of a vulva pad and keeping the hands away from the genitals should be given due attention. In schools separate toilets should be provided for these children and this could only be carried out by invoking the aid of the Board of Health. Teachers and social workers should be taught that this situation was always present among children and that the method of acquiring the gonorrheal discharge was in most instances innocent.

Complement Fixation in Gonococcal Infections.—Dr. Archibald McNeil read this paper. He described the technique of the complement fixation tests for gonorrhea which was identical with that of the Wassermann test for syphilis, with the exception that the antigens prepared from pure culture of gonococci were used. In cases of anterior gonorrheal urethritis in the male and acute vulvovaginitis, a positive reaction was practically never obtained. Shortly after the posterior urethra in the male and the cervix and the glands of Bartholdi were involved, the serum of the patient reacted positively. After having tested between three and four thousand sera taken from persons suffering from all varieties of gonorrheal infection, the results seemed to justify the assumption that a positive reaction denoted the presence of recent activity in the body of a focus of living gonococci. A positive reaction persisted for from six to eight weeks after a cure had been effected and it had also been found that antibodies disappeared from the blood of rabbits immunized to the gonococci in about the same period. While one negative result would not be accepted as conclusive evidence of cure, when persistently negative results had been obtained extending over a considerable period of time, it seemed safe to assume that a cure had been effected. A detailed statement of results of tests in eight cases of vulvovaginitis in children showed that infantile vulvovaginitis might be more than simply a local infection and that the infection might be active after all local manifestations had disappeared. In acute cases of vaginitis where the blood was negative, and there was any doubt with regard to the identification of the gonococcus as the causative organism antigens might be prepared from pure cultures of the suspected organism from the case and tested against a known antigonococci serum. This test was very specific. With the present methods there was no cross fixation even with gonococcus antigen and an antimeningococci serum, or with a meningococcus antigen and an antigonococci serum.

Dr. Roland G. Freeman believed that the disease, vulvovaginitis, needed more attention than was given it at present because of the many difficulties that were connected with it. It was well known that the children in the tenements with vulvovaginitis had great difficulty in getting into hospitals because it was so well known that this was a disease that spread very rapidly and was very difficult to get rid of. Even at the Mount Sinai Hospital these cases ran along sometimes six months before being cured. With regard to the local treatment, one remedy was changed to another; today, however, with the use of the endoscope, they obtained better results by the treatment of these cases with stronger agents than formerly. The vaccine treatment seemed to be plausible and many men in institutions seemed to believe that its use resulted in much good.

Dr. Charles G. Kerley said he was glad to learn that they were working in the right way in order that they might investigate the subject from every standpoint. The last speaker had started out without any preconceived idea, and therefore no preconceived idea had been worked out his way. He had had the opportunity of offering much upon this subject, the management and the problems con-

nected with it, and he apparently was going at it in an open-handed manner. The subject under discussion was certainly a very troublesome one to all and he was very much interested in hearing the results of the careful observations made by Dr. Murphy. Dr. Kerley referred to some thirty-six cases that reached one of the institutions he was connected with; they all had a vaginal discharge and Dr. Hamilton was called upon to suggest a way to be employed for successful treatment. Fifty million of the dead bacilli were started with and this was increased, the injections being given at five day intervals; this was of the stock vaccine. Most of these patients were under three months of age. Sixteen patients received from 350,000,000 to 1,000,000,000; three from 1,000,000,000 to 10,000,000,000; three from 3,000,000,000 to 4,000,000,000; in six, 6,000,000,000 of the dead bacilli were given. From his results it was seen that the vaccine treatment did not offer much; the discharges continued but they could be kept partly clean by douching methods. They made as good a recovery as though the vaccines had not been given at all. In other words, the use of the vaccines did good for a short time only. Dr. Kerley had treated hundreds of these cases with disinfectants, irrigations, and everything that might keep the vagina clean, and he now was using a douch, three times a day, of not less than a quart of water; after drying the parts thoroughly he applied a powder of boric acid, starch, and a preparation of zinc. These patients seemed to do as well as those that were irrigated with various solutions. Many of these patients, after being treated in various ways for months, seemed often to be cured spontaneously. He believed that the disease was a self-limited one. It seemed to occur during the runabout period of the child's life, a period which made in fact the vagina less habitable for the gonococci. Many children were found to be at this period immune.

Dr. Henry Koplik said that he had read of the work they were doing in the Boston City Hospital and thought they were working in the right direction. Children with gonorrheal vulvovaginitis infected other children. The disease was a mild form of pest and even children in better circumstances became infected by the use of towels or manipulation as the case might be. There was no doubt but that these cases of vulvovaginitis were self-limited, but at the same time it should be remembered that they infected others. At Mount Sinai Hospital there were four cases of fatal gonorrheal peritonitis, the infection occurring through the vagina. One never knew when the disease would flare up and become dangerous to life. Children afflicted with this disease should be kept apart from other children. The subject did not receive the attention that it should receive, but he believed that eventually the proper authorities would take it up. The real question was to find out how these children became infected. In the wards of hospitals where every conceivable precaution was taken one or two cases of vulvovaginitis would crop out. It was not right or proper for institutions to keep patients away because of this disease. At Mount Sinai Hospital they received these children, but took certain precauations. They also discharged children that they knew had the disease and after careful observation he had concluded that these children rarely infected others. With regard to the vaccine therapy, he did not believe that these children could receive so many million of the dead bacilli and expect a cure. They were in a position where the treatment of this disease was far from efficacious. They were in no position ot sit down and treat cases in the wards of the hospitals unless they were permitted to as Dr. Barnett had done. At the Good Samaritan Dispensary they could not approach these children without a certain amount of timerity. They had used the endoscope with good results. He had observed some of these cases from birth until they were married and they were not sterile and they did have children. There was no doubt but that this disease sometimes led to serious consequences and was a pest in the public schools. There was no doubt but that many of these cases resisted practically all methods of treatment, and these seemed to be cases of mixed infection. The Board of Health should take cognizance of this disease especially when it occurred in public schools.

Dr. Henry Dwight Chapin said that there was some difference between the action of the gonococci as seen in infants and young children and that seen in adults. They rarely saw an infection of the eyes or tubes in children, and he recalled but one instance in which the ovarian tube had to be removed because of this disease. It might be possible that gonorrhea in the young was usually produced by a different strain of gonococcus.

Dr. Martha Wollstein said that gonorrheal vulvovaginitis was approached from the prophylactic standpoint at the Babies Hospital where they thought that they had almost solved the problem by means of the greatest possible vigilance; the slightest relaxation of this vigilance was invariably followed by disastrous results. Every girl baby who applied for admission had a smear taken from the vagina and this was at once examined in the laboratory. If pus cells or gonococci were found, the child was not admitted unless she was so ill that she needed immediate attention. In such a case she was isolated. During the past year sixty-three admissions were refused for this reason. Vaginal smears from all girl patients in the hospital were examined once a week. Some years ago they had an epidemic in spite of all their precautions and they had used both autogenous and stock vaccines but the results were not encouraging. Dr. Spaulding had called attention to the long periods of latency as well as to the numerous recurrences among prolonged cases of vulvovaginitis and cases were no doubt admitted to the hospital during this latent period. Again a child might be admitted to the hospital in the first stage of the disease and the smears would not show a positive reaction until a week or ten days later. Simple vaginitis occurred rarely as compared with gonorrheal vaginitis, but there were some cases which were undoubtedly due to streptococci or staphylococci. These cases cleared up readily and did not have the recurrences characteristic of the gonorrheal cases. The smears must be taken from within the vagina and must be free from stool contamination.

Dr. H. B. Wilcox, reporting the experience at the Children's Service at Bellevue, said that though there was a ward devoted to the treatment of vaginitis there, the main therapeutic effort at that institution was therapeutic. All the methods of treatment mentioned in the discussion had been tried more or less thoroughly at Bellevue. The disease had been controlled but it had not been cured. No success had followed the use of commercial vaccines. Although difficult to obtain the material, it was thought that autogenous vaccines offered the best means of permanently eradicating the trouble. No permanent success had resulted from lactic acid gauze packing, argyrolor iodine suppositories. Prompt relief from the profuse discharge and the discomfort attending on it was obtained by douching with potassium permanganate, and daily argyrol suppositories. This was the present routine treatment at Bellevue. On admission smears were taken and must show neither cellular elements nor bacteria during the three days detention in the admission ward before the children are sent upstairs to the ward. The method of taking these smears was most important. Often with a negative smear from the introitus gonococci were found in great numbers in the vault of the vagina or the cervix. The cases that escaped detection on admission later became the sources of ward epidemics and were usually those which had had only a superficial examination. The use of a small speculum, enabling one to reach the vault of the cervical canal directly, should be insisted upon, and negative cultures taken in any other way were considered as non-conclusive. If such care was used in obtaining material for examination most cases of simple vaginitis could be demonstrated to be due to gonococcus infection. Seldom were any complications of the disease noted on this service.

Dr. Louis Fischer said that at the Willard Parker Hospital they handled hundreds of these cases of gonorrhoeal vulvovaginitis. Probably ten per cent. (10%) of those admitted with scarlet fever had the disease. These cases were very distressing to those who had to care for them whether treated outside or in the hospital. Dr. Huddleston had used stock vaccines but the results of this treatment were not at all gratifying. At the present time they were using local treatment, irrigations of magnesium, of alum, and of plain water. In a large series of cases that had bothered him for some time, he obtained good results by instituting a treatment in the form of arsenic and cod-liver oil. He found they were greatly benefited by the use of cod-liver oil, arsenic, iron and sometimes by a change of air.

Dr. B. Wallace Hamilton, who had treated 900 cases of valvovaginitis at the Vanderbilt Clinic, said that he had been very much interested in what had been said regarding the use of the vaccines and in Dr. Barnett's treatment of gonorrhaeal vulvovaginitis in young children. He was also interested in hearing the statement made that this was a self-limited disease; but this latter statement he was going to question. He had seen many cases that came to the clinic after the disease had run a long time, even two years or more that still were not cured. He was impressed with the fact that some cases would recover without any treatment whatsoever. Keeping the vagina clean and instructing the mother would help them in the care of these unfor-

tunates. In children having but a short duration of the disease excellent results were obtained from the use of vaccines and without any local treatment whatever. But if the case was of long duration the results of the vaccines was not so good. However, what had been accomplished by the use of the vaccines in gonorrheal vulvovaginitis offered them great hopes. There were many cases that would not do well under vaccine treatment, nor under any treatment whatever. He was still very enthusiastic over the use of vaccines.

Dr. George Dow Scott said that the average physician didnot give vaccine treatment the place that it deserved, many thinking that the vaccines were of no use at all. In the treatment of certain arthritides the use of the vaccines often gave excellent results. An important point in the treatment of these cases was the following (and he did not think he should be subjected to ridicule for bringing it up): After washing out the vagina with water it should be flushed with pineapple juice, which was a splendid sterilizer of the vagina. This in his hands had given excellent results.

Dr. Nathaniel Barnett, in closing the discussion, called attention to the fact that by endoscopic examination one could almost make the diagnosis without smears. In gonorrheal cases the cervix had an entirely different appearance than that in the normal child.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held at the New York Academy of Medicine, April 1, 1913.

The President, Dr. Smith Ely Jelliffe, in the Chair.

A Case of Syphilitic Osteitis and Periosteitis of the Skull.—Dr. M. S. Gregory and Dr. M. J. Karpas reported this case and showed the specimen. The patient was a German woman, married, 45 years old. She was temperate and gave no history of syphilis or of sinus or aural affection. The family history was negative. The patient enjoyed good health in infancy and childhood and was married when she was fifteen years and four months old. She had four children: two of these died, one at the age of three of cholera and the other at the age of seven months of jaundice. There was no history of miscarriages, and no direct nor indirect history of syphilis could be determined. The Wassermann test in the husband was negative. The patient ceased to menstruate at the age of 44, and had been sterile for the past twenty-seven years. It was stated that after the birth of each child she would become very obese. There was no history of trauma. The patient enjoyed excellent health until seven years ago, when she was operated on for gallstones, and three and a half years later she had an attack of malaria. In July, 1909, she complained of pain and swelling in the left knee and right thigh. She began to have difficulty in walking and was put to bed. Occasionally small growths would appear on the scalp, which would disappear without treatment. For more than ten years she had suffered from terrific headaches, which persisted all the time. In March, 1911, she lost her hearing in the left ear, and about the same time the left side of the face became paralyzed. No definite date could be fixed for the paralysis of the left external rectus. During this time the patient had received active antiluetic treatment, including mercury, potassium iodide and salvarsan. On March 31, 1912, she had a convulsion which was limited to the face and upper extremities, and it was then noticed that the left eyeball became bulging and that the sclera was congested, but the cornea was unaffected. On the following day she had a similar convulsion, after which she became drowsy and fell asleep, and when she awoke she was delirious, spoke in a rambling manner, said that she saw cats, etc., and her general behavior was irrational. The patient was admitted to the Psychopathic Department of Bellevue Hospital on April 1, 1912, in a delirious and excited state, which subsided in a few days. During her stay in the hospital repeated neurologic and somatic examinations were made, of which the following is a brief summary: The patient was poorly nourished and cachectic, with a flabby musculature and dry skin. She was somewhat anemic and her general physical condition was very poor. She was a bedridden invalid, requiring constant care and attention. The heart's action was weak and irregular; there was some evidence of chronic nephritis and of a tubercular process at the left apex. The arteries were not thickened.

Neurological status: Smell was apparently intact; exophthalmus, especially of the left eye; purulent keratitis of the left cornea; the left pupil was covered by a purulent film, and for that reason its motivity could not be determined. The right pupil reacted to light and accommodation, and the sympathetic reflex was intact. There was no evidence of paralysis of the ocular muscles excepting the left external rectus. The optic discs were normal. There was a posterior stapheloma. The left corneal and conjunctival reflexes were abolished, but the touch sense was not affected. The left side of the face was paralyzed; the mouth was drawn to the right, the nasolabial fold was obliterated and the tongue deviated to the right. Hearing on the right side was good; that on the left was poor. The other cranial nerves showed no pathological condition. There were no sensory disturbances nor evidences of pyramidal irritation. The reflexes of the upper and lower extremities were active; the abdominal reflexes were absent. The patient was unable to assume a sitting or a standing posture, and she could not walk. There was some difficulty with coordination on the left side. The spinal centers were not under control. The Wassermann test in the blood was negative. The cerebrospinal fluid showed no increase of globulin nor complement-deviation; there were only ten lymphocytes per cm. When the patient was admitted to the hospital she was confused, restless, and complained of terrific pains in the head and left eye, which at times were so intense that she cried loudly and showed considerable agitation. She had several convulsions, which were usually general; some were severe; others mild. She spoke in a rambling manner, claiming that she saw animals, etc. Her speech was often unintelligible and her answers irrelevant. She was depressed and agitated, but after a few days she became quiet and composed and was able to give a fairly good account of herself. She was clearly oriented, maintained that she was sick, complained of terrific headaches, and showed a very good insight into her physical disorder. Her general mental condition showed but little variation; only when her headaches were very marked she would become restless and agitated, and on several occasions she was somewhat delirious and hysterical. Shortly before her death, which occurred on May 16, 1912, she became very delirious, spoke unintelligibly, had hallucinations, and was irrelevant in her replies.

Dr. Morton E. Hall, pathologist to Bellevue Hospital, gave a detailed report of the pathological-anatomical findings in the case reported by Drs. Gregory and Karpas. The autopsy in this case was performed by Dr. Charles Norris, and the anatomical diagnosis was as follows: Chronic periosteitis and osteitis of the frontal, parietal, and occipital bones and the petrous portion of the left temporal bone (spyhilitic). Chronic pachymeningitis of the left middle fossa. Chronic mastoiditis and otitis media (syphilitic). Lobar pneumonia. Chronic cellulitis of the tissues of the scalp (syphilitic). Chronic interstitial hepatitis (syphilitic). Anemia. The anatomical diagnosis was confirmed by the pathological findings. In this and in a second similar case that had come under Dr. Hall's observation it was interesting to note the worm-eaten type of osteitis, and both cases showed marked suppurative changes, with elevation of the periosteum. There were no evidences of cerebral infiltration and the spirocheta was not definitely demonstrated in either case.

An Anomalous Case of Acromegaly.—Dr. M. Neustaedter presented this case for Dr. Edward D. Fisher. The patient was a Russian, 30 years old, a peddler, whose family history was unimportant with the exception that he had one brother who was suffering from multiple sclerosis. The patient was married but his wife had never been pregnant. Up to a year ago he was slightly alcoholic. Eight years ago he had gonorrhea; denied lues. Four years ago he began to have trouble with his eyesight, which constantly grew weaker. Three months ago he began to suffer from headache, which was constant up to a week ago. He had never vomited nor suffered from nausea. About ten weeks ago his speech became affected, and at the present time he also complained of "drawing" pains in his limbs, especially in the left leg. He became depressed and began to lose his memory, especially as to recent events. He was always sleepy and rather irritable. His gait, which was formerly slightly ataxic, was now fairly good. He was constantly gaining in weight in spite of his poor appetite and had gained fifteen pounds in three months. Physically he was well nourished. There seemed to be a beginning deposit of adipose tissue around the hips. His hair, as compared with a photograph taken three years ago, was becoming rather sparse and coarse, and this was also true of the hair in the genital and axillary regions. The skin was thick and moist. The lower jaw was becoming enlarged, as shown by the *x*-ray of Dr. L. T. LeWald, and the bones of the fingers were becoming

thickened. The sella turcica was slightly enlarged and about 5 mm. in diameter. His speech was rough and deeper than formerly; it was protracted and at times even rambling. His movements were rather clumsy, lacking energy, and he complained of sleepiness. His hearing was not affected. There was a marked impairment in his sense of taste on the left side of the posterior two-thirds of the tongue. Smell was much impaired on the right side. There was evident exophthalmus; the pupils were dilated, irregular in shape and unequal, the right being the larger. They failed to respond to light or accommodation. There was a left staphyloma and a double choroiditis. The patient also presented a binasal hemianopsia, a myopia of seven diopters, a haziness of the vitreous and detached retina on the temporal side of both eyes. There was a fine intention tremor of the hands and tongue. The superficial reflexes were present and lively; the knee jerks were exaggerated; there was no Babinski nor clonus. The motor power of the flexors of the left arm and leg was somewhat diminished. The Wassermann reaction was very strongly positive.

Dr. Edward D. Fisher said that while this was not a well-defined case of acromegaly, the *x*-ray findings pointed rather strongly to that diagnosis. The enlargement of the sella turcica, as shown by the *x*-ray, was rather peculiar, and differed from what we would expect to get in a tumor of the pituitary body. It showed, however, as the eye findings would indicate, the presence of a growth in that region, which spread beyond the sella turcica and probably involved the chiasm. The general characteristics of the case pointed to a tumor of the pituitary body. The man had improved somewhat under large doses of potassium iodide. In its present stage, the case was a questionable one of acromegaly. If the symptoms, particularly the loss of sight and the mental condition, became more pronounced, the advisability of an operation might be seriously considered.

Dr. William M. Leszynsky said it was rather unusual to have a binasal hemianopsia with a lesion of the pituitary body; a bitemporal hemianopsia was the usual condition found. To produce the former a lesion involving the external fasciculus of each optic tract was necessary.

Juvenile Paresis.—Dr. Smith Ely Jelliffe presented a girl 15 years old, whose birth was apparently normal and who developed normally as far as walking and talking were concerned. Her parents stated she had always been backward in reading. About four years ago she began to have pains and stiffness in her legs, and attacks which were called "fits," during which she would become rigid but did not lose consciousness. About this time there was an apparent retrogression in her mental development, and since then she had slowly deteriorated. Neurologically, she showed the Argyll-Robertson pupil, a tremor of the tongue and face, an infantile mode of speech, with a degree of hesitation that almost amounted to stuttering, and a loss of knee jerks. These symptoms, briefly stated, had led Dr. Jelliffe to regard the case as one of paresis of the juvenile type. The girl's father died at the age of 42 after a maniacal attack, and was a paretic. The mother has Argyll-Robertson pupils. The patient had Hutchinson's teeth. A further exposition was promised.

Dr. B. Sachs said he had a distinct impression that juvenile paresis was an extreme rarity. In the case shown by Dr. Jelliffe there was possibly a congenital syphilitic condition, and consequent mental deterioration. The findings, as given by Dr. Jelliffe, were not sufficiently definite to base the diagnosis of juvenile paresis upon them. The child's speech did not strike him as paretic in character, and the speaker said he would be inclined, in a case of this kind, first of all to try the effect of energetic anti-syphilitic treatment and see whether her condition would not be improved thereby.

Virchow-Robin Lymph Spaces in Paresis.—Dr. Jelliffe showed some illustrations of the findings that Achucarro and Snessarew had reported relative to the development of new connective tissue about the perivascular and Virchow-Robin lymph spaces in paresis. They indicated that the lymph spaces became completely organized, so that in the brain of the paretic a very grave alteration in the lymphatic circulation must result. Just at what stage of the disease this infiltration takes place; just how extensive it was, and just when it reached its maximum have not yet been definitely determined. These connective tissue changes in the brain, Dr. Jelliffe said, probably had an important bearing upon the difficulty encountered in the successful treatment of paresis. We were aware of the difficulty with which antisyphilitic remedies penetrated or circulated within the brain tissue, which would indicate that grave metabolic disturbances were brought about by the inability of the lymphatic circulation to carry on its function. At the last meeting of the Society, Dr. Moore demonstrated the presence of the *Treponema pallidum* in the brain and showed that this organism lay at a considerable distance from the blood vessels and the lymphatic channels. The problem of therapy, therefore, is not only that of the inaccessible spirochete, but also of the blocked lymph space. This latter fact is possibly largely responsible for the diffuse and uniform parenchymatous degeneration which is so manifest in paresis, in contrast with the vascular localized disturbances of the other types of cerebrospinal syphilis.

The Direct Treatment of Syphilis of the Central Nervous System.—Drs. Homer Swift and A. Ellis presented this paper. Syphilis of the central nervous system was one of the most important manifestations of a chronic infectious disease. The discovery of the *Treponema pallidum* in general paralysis by Noguchi and Moore had enabled us properly to classify this condition, so that parasyphilis today must be regarded as active syphilis of the central nervous system. If, in any disease, we had an etiological agent present and still active, and if we had specific therapeutic agents to use against the microorganism, it seemed rational to apply the drugs until all evidence of activity of the virus was removed. Syphilis of the central nervous system was one of the most resistant forms of the disease to treatment. The symptoms were often mechanical and improved or disappeared when treatment was applied, but the entire eradication of the disease was most difficult. These difficulties were increased by the anatomical peculiarities of the central nervous system. The perineuronal lymph spaces and the perivascular lymphatics were the sites of the most intense round-cell infiltration. These spaces were directly connected with the subarachnoid space. Drugs and antibodies were but little eliminated into the cerebrospinal fluid, so that treatment intravenously only reached the disease on the side of the blood stream. Attempts to introduce salvarsan by means of lumbar puncture had resulted in intense irritation of the meninges in monkeys. Serum was practically the only substance known which it was safe to introduce repeatedly into the subarachnoid space. It had been shown that the serum of patients who had been treated with salvarsan had definite effect upon the spirochetal diseases: (*a*) clinically on congenital and secondary syphilis, (*b*) by inhibiting the growth of *Treponema pallidum* in cultures, (*c*) by inhibiting the growth of the spirochete of relapsing fever in mice, and (*d*) clinically in central nervous syphilis by introducing serum directly into the subarachnoid space. The technique employed was to treat the patient intravenously with salvarsan or neosalvarsan, one hour later withdraw 40 to 50 c.c. of blood into a sterile centrifuge tube, centrifugalize the blood, and separate the serum from the clot. Twelve c.c. of the serum was diluted with 18 c.c. of normal serum and heated to 36° C. for one-half hour. A lumbar puncture was made and spinal fluid withdrawn until the pressure was reduced to 30 mm. of cerebrospinal fluid. The 40 per cent. serum was then injected by gravity through the lumbar puncture needle.

Professor K. Heilbronner of the University of Utrecht, who was invited by the President to open the discussion on the paper of Drs. Swift and Ellis, said he could only thank the Society for the privilege of being present, and of having had the opportunity of listening to this very interesting presentation of the subject of treating cerebrospinal syphilis by a new and direct method.

Dr. John A. Fordyce (by invitation) said that while he felt a certain amount of hesitation in discussing the treatment of syphilis of the nervous system before neurologists, yet his experience with these manifestations of the disease from the standpoint of a syphilographer might prove of some value. He wished to say at the outset that he had had no experience with the intraspinous method of treatment as described in the paper by Dr. Swift and Dr. Ellis, but he had had during the past two and one-half years considerable experience with salvarsan given intravenously in syphilis of the cerebrospinal system. Although many of the nervous manifestations of syphilis occurred several years after infection, in the great majority of cases, if not in all, involvement of the cerebrospinal system took place during the secondary stage of the disease. It was at this time that there was a generalized dissemination of the spirochetes. Dreyfus had demonstrated that during this stage more than 50 per cent. of cases of syphilis showed some evidence of involvement of the cerebrospinal fluid, frequently without giving rise to symptoms. It was reasonable to assume, therefore, that the infecting agent might remain latent in the cerebrospinal fluid for years, but under the influence of various contributing factors, it could cause during this stage, or later, meningitis, paresis, or the complicated clinical picture of cerebrospinal syphilis.

From the histories of patients who came under his observation with tabes or other forms of cerebrospinal syphilis he was impressed with the frequency with which these patients stated that they had had months or years before ocular paralysis or other manifestations of meningitis. During the early experiments with salvarsan as a therapeutic agent Dr. Fordyce said it was thought that one or two doses of the remedy would be sufficient to control the infection, and unfortunately this impression was still held by many practitioners and fostered the belief that salvarsan was not effective in the treatment of syphilitic conditions of the cerebrospinal system. As a matter of fact we now know that many of these cases were aggravated by one or two doses, while on the other hand many of their symptoms were relieved by the persistent use of the drug. It was a common experience with him to see an aggravation of the tabetic symptoms produced by one or two doses of the drug, but by persistence in its administration, the pains, crises, bladder symptoms, and general nutrition of the patients were often greatly benefited. The speaker said that this plan of treatment in these cases was to give injections of salvarsan at weekly intervals, combining them with mercury at intervals of three or four days. In one case he gave 21 injections of salvarsan, about 10 grams in all, with marked alleviation of the symptoms, in a patient who had come to him with the diagnosis of paresis. The Wassermann reaction in this case had not been influenced by the treatment, and his cerebrospinal fluid at the last examination contained 90 cells, with a positive Wassermann and globulin reaction. He was inclined to believe in this case that the intraspinous method of Dr. Swift might prove of distinct benefit. Dr. Fordyce said that he was becoming more and more convinced that salvarsan had no deleterious effect on the optic nerve. On the contrary, he had now had two cases under his observation where it had proved distinctly beneficial. In one of these cases the visual fields had enlarged, and whereas before the treatment the patient could not count fingers before one eye, she can now distinctly recognize features with the eye. In closing his remarks he again emphasized the importance of persistent treatment with salvarsan and mercury if we wish to permanently benefit these cases and influence the pathological changes in cerebrospinal fluid.

Dr. SACHS said he had listened with much interest to the paper of Drs. Swift and Ellis, and that he, with others, would hail with great satisfaction any method that would render the treatment of syphilitic diseases of the cerebrospinal system more successful than it had been heretofore. The theory upon which this method of treatment was based was surely a plausible one, and appeared to exert a direct effect on the syphilitic process in the central nervous system. Whether the change in the globulin content and cell count necessarily indicated an improvement in the patient's condition would have to be determined by a much longer experience with this method of treatment, and the results would be watched with great interest by clinicians. Dr. Sachs said that in the treatment of syphilis of the central nervous system with salvarsan, he had been struck by several points. One was that the persistence of the Wassermann reaction, both in the blood and spinal fluid, seemed to be out of relation to the intensity of the morbid process. While he was glad to have the assurance of Dr. Fordyce that we had given the salvarsan altogether too infrequently and in too small dosage, still a word of caution was in order, lest we should go from one extreme to the other. Women, apparently, did not tolerate as large a dose as men.

Dr. FISHER said that in the early days of salvarsan he was opposed to its use in general paresis and tabes; upon the strength of more recent reports, however, he had employed it in parasyphilitic conditions to a considerable extent, and in no instance could the results be regarded as marvelous. In certain cases, of course, we could not expect it to do more than to relieve the pains and possibly some of the ocular symptoms. He had found it more effective in those cases which we had clinically designated as cerebrospinal syphilis, in which the pathological changes differed from those of general paresis or tabes, although the differential diagnosis was often obscure.

Dr. D. M. KAPLAN said that in the tables shown by Dr. Swift one could observe that in the majority of the cases the cell content became normal much sooner than the positive Wassermann disappeared. In the majority of cases, the condition was improved in spite of the fact that the Wassermann remained positive. We had come to regard a positive Wassermann as an indication of a still existing syphilis, and until it became negative we could not look upon it as a cure or even an amelioration. It seemed to him, the speaker said, that the use of a large quantity of spinal fluid tended to make the positive Wassermann a persistent factor, regardless of the fact that the other serological tests became negative.

Dr. I. STRAUSS asked Dr. Swift whether the results of this treatment, as shown by the tests of the cerebrospinal fluid, had been compared with those in cases that had been treated only with salvarsan. Also, whether any improvement in the objective signs had been observed following this method of treatment, or whether they only improved subjectively. We knew that tabetics were very apt to be helped by any new method of treatment. Also, whether Dr. Swift had had an cases that showed toxicity due to the continuous use of the salvarsan, and if so, how long he would wait in such a case before repeating the dose.

Dr. SWIFT, in closing, in reply to Dr. Sachs, stated that the warnings of Ehrlich had been heeded, and the dose of salvarsan had been reduced in treating women. The dose for women was usually one-tenth of a gram less than that for men. In carrying out the direct treatment, Dr. Swift stated that the patients usually received five or six injections at intervals of two weeks. If intravenous treatment alone was given, weekly injections were used. In those cases where, as the result of treatment, the cerebrospinal fluid had been reduced to normal with a negative Wassermann reaction, there had been no further progression of the tabetic symptoms. From this we might expect that if these patients had been treated in a sufficiently early stage, there would have been hope of permanently arresting the disease at that time. In answer to Dr. Strauss the speaker said they had not seen much improvement in the objective symptoms in their cases, and he knew of no instance where the knee jerks returned once they were gone.

The Newer Histopathology of the Cortex in the Psychoses.—Dr. H. A. COTTON of Trenton, N. J., made some remarks on this subject, which he illustrated with the aid of colored lantern slides. He emphasized the fact that there was a general feeling that there had not been much encouragement in the study of the histopathology of the cortex in the psychoses. This he thought was a false impression. Much had been done in paresis, and the recent discoveries of Noguchi and Moore showed the necessity for persistence in the work in connection with other diseases, such as dementia præcox, to which his own pathological studies had been largely limited.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DIAGNOSIS AND TREATMENT OF KNEE LESIONS IN THE ADULT.*

By V. P. GIBNEY, M.D., LL.D.

NEW YORK.

The president of the association, soon after his election, was good enough to invite me to attend this meeting, and to prepare a paper for your discussion. An intimacy extending beyond a period of forty years prompted me to accept this invitation, and I can assure you, gentlemen, that the honor of meeting the members of the Kentucky Medical Association is one that is deeply appreciated by one born and reared in old Kentucky. I recall a meeting in Danville many years ago where it was my distinction to be seated on the platform when that eloquent Kentuckian, the late Richard O. Cowling, presented to that giant in surgery, Samuel D. Gross, the door-knocker that had hung on the front door of the father of ovariotomy, Ephraim McDowell.

The profession of this State has always occupied an exalted position in the medical world, and it has always been a subject for self-congratulation that my medical education was begun in the Medical Department of the University of Louisville.

In selecting a topic which I thought would at least elicit a discussion, I have had in mind the one idea—something practical. The topic I have chosen is one dear to my heart, obtruding itself on all occasions, and when casting about for something which might interest my friends in Kentucky I had quite forgotten a vacation incident in the early part of the century. Indeed, I had already chosen my title and sent it to my friend and one time pupil, Dr. Arthur T. McCormack, and had written the introductory, while enjoying my vacation on the shores of Long Island Sound, when my secretary sent me a lot of reprints of papers on this very subject. I found one with this title: "Diagnosis and Management of Some of the More Common Lesions of the Adult Knee," extracted from the *Washington Medical Annals*, 1902.

In February of that year, while I was taking a rest at the New Willard in Washington, a delegation from the Medical Society of the District of Columbia invited me to present a paper for discussion. In reading that old paper I find that I have become a little bolder in treatment and a little more confident in diagnosis.

The temptation was very strong to treat you as many of the circuit riders in my early Kentucky days treated their congregations, viz., fish out an old sermon and "let it go at that," on the ground that the faithful followers of the Meek and Lowly never tired of the old, old story.

You may rest assured, brethren, that I am giving you a "brand new sermon."

The knee-joint is as important a joint as any one in the human mechanism, and demands recognition in every period of life. If a babe in arms is poorly fed and scorbutus results, subperiosteal hemorrhages frequently involve the periosteum bordering on the knee, and alarming symptoms and signs call for prompt measures of relief, lest the functions of the joint be hopelessly impaired. When the little one begins to walk and the second summer is passed, the bacilli of tuberculosis of the bovine type in their migratory wanderings prefer to colonize often in the distal femoral epiphysis, or, the proximal tibial epiphysis, when these cancellous structures become hyperemic because of trivial traumata and a tuberculous knee, formerly known as a scrofulous knee, or, a tumor albus, develops, most insidiously, making alarming headway, while the family physician is casting about for a diagnosis.

During the period of adolescence in this commendable athletic age, traumata on the tennis court, the diamond, the football field, or in the mountain passes bring about the various forms of internal derangement of the knee, and errors in diagnosis contribute not infrequently to a crippling condition extending well into adult life.

Later still, when adolescence has passed and when a vocation has been chosen, long hours at a desk in ill-ventilated quarters, with irregularity of meals, efforts at keeping up social requirements induce changes in the alveolar processes and impairment of the digestion and static disturbances in the pedal extremities, we come face to face with the many forms of infections and the knee often is obliged to bear the brunt of the invasion of the pathological cocci with which the research laboratory has made us so well acquainted.

Lesions of the knee in adult life have always interested me quite as much as have those in childhood. Hospitals have been founded in all parts of the world for the crippled child, while few have opened wards for the adult cripple. The reason therefore is simple enough. The helplessness of childhood appeals to the public, and the maternal instinct predominates.

No argument is needed to convince this association of the importance of an early recognition of exact lesions which bid fair to cripple the wage-earner or his equally important helpmeet in the struggle for existence.

*Presented at the meeting of the Kentucky State Medical Association, Bowling Green, September 2, 1913

The diagnosis presupposes an intimate knowledge of the anatomy of the joint, deep as well as superficial. One needs to recall the outline of the lower end of the femur and the spines in the center of the upper end of the tibia. These articular surfaces are admirably adapted one to the other for the ginglymoid action. The location and function of the semilunar cartilages and their relationship to the ligamentum alaræ need to be remembered, as injury to these, either by trauma or infection, induces a good deal of Internal Derangement. It is essential that one should bear in mind the spines of the tibia and their relationship to the crucial ligaments, for I am convinced that a diagnosis is not often made of a fracture of one or both of these spines which we see standing out so prominently in all of our *x*-ray plates. One should study the normal size and outline of these processes and become thoroughly familiar with their function, so that any blurring in the plate or any markings suggestive of a partial or complete fracture can be easily recognized. It should be remembered, too, that the attachments of the crucial ligaments close to the bases of the spines could easily be detached by avulsion or fracture. Given then an ability to recognize these anatomical disturbances, a closer investigation as to the nature of the trauma and the functions of the joint soon following the trauma is demanded, and a diagnosis ought to be made with reasonable accuracy.

While my own histories record comparatively few lesions of the crucial ligaments or tibial spines, I am reminded now, in the preparation of this paper, of my failure to diagnosticate many cases which have puzzled me in times past and have been relegated to that class of Internal Derangements, by a most interesting paper sent me by my good friend, Mr. Robert Jones, the title of which is: "On Rupture of the Crucial Ligaments of the Knee, and on Fractures of the Spine of the Tibia," by Robert Jones of Liverpool and S. Alwyn Smith of Winnipeg, and published in the *British Journal of Surgery*, Vol. I, No. 1, 1913. Did time permit I would like to quote extensively from this valuable contribution, but I must content myself with advising all interested in this subject to study the plates, the cases, and the text of the paper.

Among my records I have the following:

Case I. (*No.* 4437) of rupture of the crucial ligaments I made out in 1898. The patient was a distinguished Laryngologist, 52 years of age, who injured the ligaments by fancy riding in the ring a few months before he came under my observation. There was a laxity of the joint, preventing a subluxation laterally in full extension as well as in partial flexion. By limiting these movements in the lateral direction with an apparatus, relief was obtained.

In studying the cases in the paper to which allusion is made, one cannot help arriving at the same conclusion the authors do, viz., "In a case of recent rupture of one or both crucials, fixation of the knee for a period of from three to six months offers the best chance of recovery, and that immediate operation should not be resorted to."

And that "The rupture of any of the ligaments of the knee should be treated by absolute rest until healing is complete. This, of course, applies with the greatest force to rupture of the crucial ligament."

If the practitioner fails to recall the instruction received in the anatomical rooms, his trusty "Anatomy" is at hand and there is no excuse for a failure to get a knowledge of fundamental points in arriving at a diagnosis.

The history of the case is the next important factor. The exact date when lameness or disability was first observed requires a little cross examination to bring out a probable trauma as the exciting cause. My own routine method in conducting this cross examination enables me to locate pretty accurately (1) the initial lameness; (2) whether pain is present when the patient is standing or walking only; (3) just where the pain is felt; and (4) whether the pain or distress persists after use and into the night.

These points being fully established, a search for other factors in the etiology follows quite naturally; such as excessive weight bearing and the strain on the muscles of the leg that would be induced by a falling arch or a poorly balanced shoe.

Should no information be obtained by the above investigation, a source of infection should be diligently sought, and with the many instruments of precision at hand one can soon determine a clue well worth folowing.

Without trespassing on your time with a didactic essay, I am sure I can convey the lessons I have to impart by illustrating points in diagnosis in treatment and in prognosis by a selection of clinical records taken from my history sheets, and very little reference will be made to bibliography.

In illustration of lesions periarticular, let me cite the case of a strain complicated by weak foot in the person of a personal friend, a distinguished author of a work on Surgery.

Case II. (*No.* 11,039). Male, aged 60, consulted me November 11, 1911, for a lameness involving the left knee, and the history elicited was that he had always been temperate in eating and drinking, and had, prior to the summer of 1911, never had any signs or symptoms of gout or rheumatism. A medical friend, an internist of high repute, had for several weeks been treating him for a gouty knee, depriving him of his after-dinner cigar, of articles of diet of which he was especially fond, and of all alcoholic drinks. I knew that he lived many months in the year on a farm in the northern part of Connecticut—the Perkshire Hills. I soon learned that he had been superintending the digging of a pond, and had been wearing rubber boots, sinking often deep into the mud, requiring quite a pull to extricate the foot. He recalled a pain in his knee after one or two of these efforts. Toward the close of the summer he found his knee tender about the head of the tibia and was himself convinced that these frequent traumata were responsible for his lameness. An examination failed to discover any actual joint lesion. The tenderness and pain were confined to the internal lateral ligament and about the origin of the tibialis anticus. There was some thickening and tenderness at the metatarso-phalangical joint—great toe. While the had a good arch (when the foot was at rest), this gave way on standing and walking. The diagnosis was made in accordance with the findings; the knee was strapped with rubber adhesive plaster, and a shoe built to fit the under surface of the foot in repose.

November 15, practically cured and happy over a return to his former mode of living. December 11, discharged cured. In the winter of 1912 and of 1913 I saw him in Augusta, Ga., and there had been no return of symptoms.

Case III. (*No.* 11,079). A gentleman, aged 26, came under my care December 10, 1911, and a diagnosis of acute synovitis with traumatic periarthritis was easily made after obtaining the following history and findings:

On stepping from a subway train to the platform, December 6, he fell into an open space, striking the lower part of the shin and knee, left side. The former was "barked" and the latter bruised a little, but not enough to prevent him walking up the steps and to his hotel and dancing all that evening, the discomfort being trifling. Next day he consulted his doctor, who dressed the shin and strapped the knee. Swelling naturally followed, and pain increased. On the fourth day I found the strapping had given no relief; he was lame; the contour of knee was far from normal; there was a moderate amount of fluid in joint; the range of motion was very nearly normal, and

the points of tenderness were at the insertion of the quadriceps tendon into the patella and over the tubercle of the tibia. These parts, it seemed to me, had been strained in his efforts at pulling his foot out of the space between the car and platform. As he was soon to sail for a position in the Embassy at Rome, I decided to rest the joint at once; so applied a plaster of Paris bandage over a skin-fitting stockinette, with knee in slight flexion, permitting him to use the limb moderately in walking.

Next day I cut a window from the upper border of the patella to the tibial tubercle, as I had not taken the precaution to pad these sensitive points, when running on the plaster of Paris.

December 18, seven days after his first visit, he was so much improved that I removed the plaster of Paris, making it into a splint for night use. The knee was strapped with adhesive plaster, and on the 26th he was discharged cured and all treatment discontinued. He sailed next day on his foreign mission.

April 25, 1912. His mother tells me that he has had no recurrence of any symptoms and is attending all the social functions connected with the Embassy. Report has recently—(this summer)—come to me that there has been no relapse.

These two cases just reported in detail presented no difficult points in diagnosis, according to my way of thinking, and the indications, for treatment were perfectly clear, the results justifying the method adopted.

Let me call you attention to an injury done the subpatellar bursa (many coming under my observation) and, when recognized early—say within a few days—the lesion responds promptly to treatment.

Case IV. (*No* 11,044). A boy, 12 years of age, was seen at his home, November 14, 1911. While playing tennis, September 14, he fell on the right knee and was obliged to discontinue playing. The rest gave so much relief that he played next day and the following; but, swelling and pain resulting, a doctor was called; the knee was strapped, and at the end of a week he was so far recovered that he resumed his tennis without the doctor's consent. The exercise served but to add additional trauma, and he was obliged to take to bed. I found a moderate enlargement of the popliteal bursa with decided enlargement under the ligamentum patella and thickening with tenderness around tibial tubercle. There was no fluid in the joint and the range of motion was very good, if carefully made. My diagnosis was traumatic periostitis and subpatellary bursitis.

A strapping with adhesive plaster, *secundum artum* soon afforded relief, and by the 24th he was so far advanced toward a cure that he was allowed to go to school. There has been no relapse.

One sees quite frequently cases of traumatic synovitis where simple measures afford temporary relief; but these measures are not continued long enough to effect a cure, and recurring traumata induce a chronic arthritis requiring more persistent protection. Take as illustration the following:

Case V. (*No.* 4,537). A gentleman from Texas, aged 25, came under my observation, April 29, 1898, with this history: A year ago sprained the right knee alighting from a buggy and was laid up for at least a month. Plaster of Paris was employed at the outset, and on its removal, a month later, nothing was done to restore the tone of the muscles protecting the joint. He was simply put on crutches, and continued their use up to the date of his appearance at my office, although a leather splint had been worn night and day, keeping the movements out of commission. Even thus protected he injured the joint twice during the year. He complained on attempts at using the limb. There was very little change in contour and the comparative measurements showed no difference in the thighs, but one inch increase directly over the knee and three-quarters of an inch atrophy of the calf. Patella was freely movable, but flexion could not be made beyond a right angle without pain, while extension to the normal limit was easily accomplished. I could detect no lesion of the semilunar cartilages.

The indications seemed clear enough, and I soon had him fitted up with a brace known as the Campbell brace, which protected him from lateral strain, distributed the strain in walking throughout the entire limb, and allowed a range of motion equal to his own. This brace was attached to the shank of the shoe, and care was taken to avoid any pressure on thigh or calf muscles. The important feature, however, in the management of the case was daily massage with active and resistive movements. The improvement was quite apparent from the start, and by the 21st of May—less than a month—the crutches had been abandoned, the pain was no longer present, and the range of motion had increased nearly to the normal. A week later he was so well advanced toward recovery that I allowed him to return to Texas with instructions to continue the brace until all traces of the injury had disappeared.

Quite recently, August 14, 1913, fifteen years later, he called at my office socially, but really to express his gratitude, and to tell me that the cure was established within a few months after his return home in May, 1898, and the knee had remained well for fifteen years. Then he bruised it one day last spring, but within a week all was well again, and there had been no further discomfort or disability.

In illustration of this same point, let me cite another case requiring more vigorous treatment.

Case VI. (*No.* 11,036.) A gentleman, 40 years of age, from New Orleans, consulted me, November 9, 1911, and my diagnosis was subacute synovitis, traumatic. He came soon after the injury, two weeks previously, playing golf. The presumption was he played in poor form different from that of our presiding officer. The wrench was pretty severe, but next day he played again and twenty-four hours thereafter had a well-marked hydrops-articuli, which persisted up to the date of his visit to my office. The measurements were: right knee, 13¾, 13¾, 12¾; left knee (affected one), 16, 16, 14½. Flexion to 90° was resisted and painful, while extension was normal.

The Paquelin cautery, light touches, followed at once by crisscross strapping of rubber adhesive plaster, leaving free the popliteal space, was the treatment adopted, and he was encouraged to use the limb in moderation. The fluid was perceptibly less within a week; but at the end of another week, while the fluid was still present, he complained of pain on use and was not much encouraged. The aspirator was used, quite emptying the joint cavity, and a skin-fitting plaster of Paris was applied. The fluid was sent to the laboratory and the report was that a serous exudate with a few blood corpuscles was all that the specimen revealed; no pus, no bacteria, and no tubercle bacilli. At the end of a week I substituted for the plaster of Paris a Campbell brace, and with the joint thus partially protected he returned to New Orleans, where Dr. Hatch continued the treatment begun in New York.

On November 28, 1912, a year later, I had an opportunity of examining the patient, and made the following note: "Quite well for at least three months; wore brace two months, and then, for the rest of the spring, the knee was strapped; in summer playing golf without pain. Knee same size as its fellow; joint functions good and painless."

Lest the records already presented give the impression that a diagnosis of an acute or a chronic synovitis is always easy, I beg to present an illustration of how one with a very large experience can easily make an incorrect diagnosis.

Case VII. (*No.* 5,133). A young lady, about 18 years of age, was referred to me by the late Dr. Francis Markoe, October 23, 1899, and I made out a "Subacute Chronic Arthritis Left Knee with Very Little Impairment of Function"; because the history obtained was: that five years ago, while bathing, was conscious of a strain from a bruise of the knee, was lame for a day or two, but a rubbing brought about prompt relief and for three months no sign or symptom was noted. Without any more injury she began to favor the limb in use, and this disability has continued without interruption to the date of my first observation. Once or twice during the five years she has complained of pain in one or the other elbow, and the case was regarded as "rheumatism," although the measures usually adopted for such cases, such as douches, medication, and a full course at Richfield Springs failed to afford relief.

The day she walked into my office there was a distinct lameness, but the range of motion was unimpaired. On flexing and extremely I could feel a rice-body-like crepitation; but there was nothing of the kind present in the other knee. The comparative measurements were practically identical. The quadriceps femoris was weaker on the left side. Because of the long standing of the lameness, I provided her with an apparatus to diminish the strain in

walking and proceeded to strengthen the quadriceps.

By the latter part of November, while she walked with more ease, she was distinctly more fatigued after moderate walking. Potassium iodide was prescribed; but this could not be pushed beyond ten grain doses without physiological effects. Massage was continued without interruption. A distinguished internist, the late Dr. Kinnicutt, helped me out in the antirheumatic medication. She attended regularly, and yet at the end of eighteen months one could note very little progress; in fact, we were disappointed, and, as she suffered very little pain or discomfort and was able to keep up with her social duties, we practically relied on time as about the best factor in therapeutics.

In the later part of 1900 she married, and in January, 1901, moved to Boston; where a consultation was held with Dr. Goldthwaite, who, after a very careful examination, wrote me that, on finding a marked spasticity in her flexor muscles, especially the gastrocnemius, he made out a "lateral sclerosis," and no real knee lesion whatever. He had his diagnosis confirmed by Dr. Walton of Boston.

In April I had an opportunity of going over the case again and noted the signs Dr. Goldthwaite had observed. The treatment advised by him was approved, viz.: a pair of plates in the shoes to give a better balance.

In due time she became a mother, and nothing active in the way of treatment was done until after confinement.

In February, 1903, I had another opportunity of examining the patient, finding the same crepitation in both knees, the same fatigue after walking. Curiously enough, however, she told me that while in the mountains the summer preceding she walked five miles without any fatigue. I had Dr. C. L. Dana see the case with me, and he made out a myopathy or dystrophy, after finding exaggerated reflexes both sides, a Babinski reflex with no reaction of degeneration. His prognosis was that it could be arrested by mild massage and avoidance of strain or fatigue.

This case, therefore, started with an apparent knee lesion induced by trauma, and proved most instructive, because of my good fortune at being able to follow it through all of the phases of this interesting neurosis.

Among the odd things happening to a knee as a result of trauma, one finds occasionally a tenosynovitis of the hamstrings and not infrequently a rupture of the tendon of the quadriceps, and I beg to report briefly one of each.

Case VIII. (*No.* 11,244). A gentleman, aet. 32, was referred to me by Dr. DeWolf of Providence, R. I., April 13, 1912, with a history of an injury to the left knee from a fall with joint in sharp flexion, and the doctor found just after the accident extreme tenderness over the external hamstring near its insertion, the joint apparently not involved. Under bandaging he got no relief and five or six weeks later underwent a course of baking in superheated air. A month afterward distinct crepitation with swelling over the hamstrings and limitation of full movements. An orthopedic surgeon in Boston confirmed Dr. DeWolf's diagnosis and advised a week's rest followed by douches, massage and electricity. After six or seven weeks' treatment and pain on use persisting, the surgeon advised an arthrotomy, under the impression that a lipoma arborescence had developed. All of this antedated his visit to me in April, when I found swelling in popliteal space on extension to 170°, lameness and fatigue easily induced. There was a moderate degree of atrophy of thigh, knee, and calf. I was unable to detect anything within the joint by palpation. My advice was massage with full extension, as all acute symptoms had disappeared. Three weeks under this treatment proved beneficial, and I found range of motion perfect, thighs and calves same size and cure about complete.

A letter from the gentleman, November 15, 1912, contained the following: "Your diagnosis was correct, the treatment you prescribed succesful; my knee is now entirely well."

As a rule swelling in popliteal space is suggestive of a hydrops-articuli because the popliteal bursa often communicates with the synovial sac, but when the sac can be found quite free of any effusion a bursitis of the popliteal may exist independently of any synovitis. The tenosynovitis in the case just reported easily explained the bursitis.

The following is hardly pertinent to the present discussion, but because of the slight flexion deformity and the lameness referable to the knee, to say nothing of the relief afforded by operation, prompts me to make a brief abstract.

Case IX. (*No.* 5,520). An elderly gentleman, aet. 70, in 1898 had a partial separation of the tendon of the quadriceps from the patela. Enough of the tendon was left to enable him to get about with a limp only. This was on the right side and he had to exercise great care to keep from falling. He took a tumble a few days before I saw him, September 20, 1900, completely separating the tendon of the quadriceps from the left patella, and his gait was awkward, indeed. The transverse depression just above the patella was so marked and the history was so clear that a diagnosis was easily made, and on my advice he entered my private hospital. Two days later, when under ether through a longitudinal incision, the torn fibers were exposed, revealing a laceration of the capsule. Part of this was removed, the rent sutured, and the ends of the tendons sutured to the patella with Kangaroo tendons. The joint was drained posteriorly and over the dressing plaster of Paris was applied. The dressing was removed on the sixth day, healing about complete, the case acting to a wish.

On November 28, two and a half months from date of operation, full active extension and flexion was made easily; he walked well; could get on and off a car without any trouble, and the cure was fully established.

The lesions of the knee calling for an arthrotomy are varied—loose bodies, torn semilunar cartilages, liponata-arborescens, or fatty fringes do not, as a rule, respond to anything short of operation. Because of the old dread of opening a joint, especially the knee joint, the older surgeons have advised against this procedure; but within the past decade there has been a decided change in sentiment, and current literature is full of successful cases, so that one hardly feels like reporting ones own successes unless the operations can run into the hundreds.

Take, for example, a discussion on injuries to the knee joint other than fractures and dislocations, at the recent meeting of the British Medical Association at Brighton, in July. Dr. A. M. Martin of Newcastle-on-Tyne presented a series of 509 operations on the semilunar cartilage. In this series he found the external semilunar was torn in only 38 cases. The common type of injury was a split from before back. He contended that the cartilage could not be torn from its attachments when the knee was extended and his cases seemed to improve.

Whitlock of Oxford was just as positive that lesions of the semilunar cartilages were always caused in partial flexion of the knee combined with external irritation. But his experience was by no means as great as that of Martin. In this discussion, which was reported in abstract (Medical Record for August 6, 1913, page 314) the concensus of opinion was that complete removal of the injured cartilage gave far better results than any attempt at suturing.

While my own experience has extended over a number of years, I have failed to collect my cases for statistical study, yet I am convinced that the opinion expressed by the English surgeons is the correct one.

My own method of handling these cases is about as follows: An attempt is made to reduce the cartilage, if it be subluxated, hold it in place with adhesive strips and reinforced with plaster of Paris for a few weeks; then apply a Campbell brace, limiting the range of motion commensurate with ordinary use of the limb, the brace preventing undue irritation or lateral displacement. In a certain number of cases this treatment is ample. Take as illustration the following:

Case X. (*No.* 2,047). A young man, 18 years of age, came under my care on the 7th of March, 1892, and I immediately diagnosticated the case an Internal Derangement

of the Knee with Occasional Subluxation of the Internal Semilunar Cartilage and Resulting Synovitis. Eight or nine months previously, while turning a somersault, he missed his footing as he came over, and the left knee was abducted rather sharply, feeling at the time something slip. He remembers this very distinctly, and puts his finger upon the place which is over the internal semilunar cartilage. He found at the time of the accident some difficulty in extending the limb, but did so very quickly, while something slipped into place. He paid no further attention to it, played tennis all the afternoon, but a half dozen times since this date, if he started quickly to run, or if he arose quickly from a sitting posture, would experience a sensation of something slipping. The pain caused thereby would last only an instant, something would slip into place, and he would be all right again. Two weeks before he came under my observation, while catching a ball, the slipping occurred again, and his recovery from this was not so prompt as before; in fact, he had not recovered up to the time of his visit to my office.

This injury was followed by a good deal of effusion of the joint—a sign of synovitis. The wound was put up in a water-glass bandage by the local physician, and a posterior splint was applied, but the cartilage was not reduced. He was able to extend the limb only to an angle of 150°; there was distinct swelling over the internal semilunar, but there seemed to be no complete subluxation. The limbs were practically the same in size. By the pressure of my thumb over the cartilage and a sharp passive flexion, followed by extension with some further manipulation, I seemed to get the cartilage into place. The treatment by strips of adhesive plaster with plaster of Paris bandage over all was resorted to immediately, and this was changed from time to time until July 11, when he was apparently well. There was no lameness, no disability. I saw him again in the fall and there was no relapse. He was attending to his athletics in college. On December 7, 1902, I had a report that he was entirely well.

What I have found as a sequence of a number of cases of this kind is a certain apprehension lest something may happen to the knee; but where a good course of massage can be secured the muscles regain their tone and nothing further happens. In the majority of cases, however, things do not go on so well, and I have found it necessary to remove the cartilage, making a pretty thorough arthrotomy. If the case has persisted for a long while, and if recurring attacks of synovitis have been the rule, I not infrequently find great thickening of the alar ligaments and fatty masses throughout the joint requiring removal. In at least half a dozen cases, in the present year, I have found fatty tumors in the joint. I could illustrate this point by the recital of complete reports from my records, but they would add nothing to the statements already made. In my own experience the all-important question with patients is the subsequent function of the limb. All have an impression that the full range of motion will not be restored, and I find it necessary to move from two to three or four times under anesthetic, following this up always with massage immediately. Often the patients object to any further anesthesia, but I am obliged to insist on more vigorous massage movements at the hands of the masseur, and patients, as a rule, prefer this to any further operative measures.

One of the most obstinate cases, I am sure, will be of enough interest to report in detail.

Case XI. (*No.* 8,158).—A lady, 51 years of age, came under treatment, April 11, 1906. My diagnosis was Chronic Arthritis of the Right Knee, Traumatic, with Lipomatous Formations and Enlarged Fringes. The history she gave me was the following:

In July, 1904, she fell on the sidewalk and apparently tore one of the semilunars. There seemed to have been a pretty sharp arthritis requiring plaster of Paris and rest in bed for a period of five months. All efforts at relief were unsatisfactory, and with this history I had no hesitation in advising an arthrotomy at once. To this she objected so strenuously that I proceeded to treat in the usual way, giving her a Campbell brace, but the operation was done within two or three months afterward and I found fatty masses about the size of one's thumb and thickening of the fringe, the cartilages remaining intact. The return of motion was tedious, on account of the pain induced; so I was obliged to move the knee half a dozen times in the next few months under anesthesia and employing massage immediately after each operation. She finally wearied of remaining in the hospital and I allowed her to return to her home in the northern part of the State, giving full instructions about active and passive movements. She learned to strap the knee very well, indeed, and continued this until all thickening had disappeared, and when I last saw her, in January, 1909, she walked without a limp, going up and down stairs naturally, with full extension and flexion to an acute angle. The limb is well developed. I have heard from time to time of the lady through mutual friends, and I am quite sure that there has been no relapse.

While preparing this paper I recall a few cases where it was necessary to do an arthrotomy two or three times, as I had failed to remove completely all offending material from the joint cavity. In my later series, however, I have had no such ill luck, because I have been most careful to explore the joint carefully and remove every tissue that might prove the least annoying.

One of the most obstinate of this type that I have had to deal with—one in which both knees were subjected to operation, not by myself, however—is the following:

Case XII. (*No.* 10,418).—A gentleman, 35 years of age, referred to me by a patient on whom I had done an arthrotomy with brilliant results, came under my treatment on the 11th of August, 1910, for a double chronic hydrops articuli. He gave this history: five years prior to this date, without provocation the right knee began to prove troublesome. He had no treatment other than an elastic knee cap; got some relief from using arch supporters; but in January, 1910, he seemed to have developed a lesion in both knees, and was operated upon by a prominent homeopathic surgeon in New York. In July—(a month before I saw him)—a second operation was done by the same surgeon.

I found fluid in the right knee, the fringes apparently a little enlarged; and in the left knee, while the contents in the synovial sac were not so thick, there was decided evidence of fluid in both knees. The popliteal bursæ on both sides were enlarged.

The treatment adopted was the cautery and aspiration of both knees. This was continued for several months with at least half a dozen tappings. He would get apparently better, and then relapse; and in 1892, early in January, I aspirated both knees and injected two and a half ounces of a 2 per cent. solution of carbolic acid, repeating this on the right knee a week later, and in three or four days the fluid had recurred, the result being unsatisfactory. On the 12th of January I drew off the left about an ounce of fluid and injected the same amount of formalin and glycerin, 2 per cent. solution. The pain was most excessive and required morphia for a day or two to give any rest. This was repeated in March, and while one knee seemed to improve, the other was not any better. When I saw him last, on the 25th of June, 1912, he was decidedly crippled, both knees were painful, and he held both in moderate flexion; he employed a cane, and was so much discouraged that he decided to give up further treatment. Recently, during the present summer, my masseuse saw him on the boardwalk at Atlantic City, and she reported that he was using crutches when not in the wheel chair.

The only comment I have to make upon a case of this kind is that the arthrotomies were not sufficiently thorough, and I reproach myself for not having repeated these operations instead of subjecting him to such long and ineffectual treatment.

Remarks on diagnosis would be incomplete without a reference to sarcoma in the neighborhood of the joint. Let me illustrate by the following:

Case XIII. (*No.* 8,289).—A gentleman, 35 years of age, consulted me June 26, 1906, and I made a diagnosis of Subacute Arthritis of the Left Knee, Probably Infectious. He told me that seven or eight months previously he had had an acute attack of rheumatism in the left arm and knee, but was not confined to bed. In February he went to Mount Clemens and took the baths a full course, returning somewhat relieved. Soon after his return, while

standing in a trolley car, the car suddenly stopped and jarred the knee, so that it felt wobbly; but he got off and walked to his doctor's office. Since that time the knee has been stiffish and sensitive. The knee could be extended to an angle of 175 with a little force, and flexed only to 90°. The measurements which I have recorded show that there was no marked difference in size; but I thought I could detect enlarged fringes beneath the ligamentum patella.

I subjected him to the usual treatment, employing a brace, and in addition to this a skin-fitting plaster of Paris because of the atrocious pain about the head of the tibia. As he got no relief, I secured an *x*-ray in August; and this and the negative showed a suspicious spot in the lower end of the femur. The pain at this time was so great that he required narcotics by day and by night. Two or three days later we thrust a scalpel into the same thickened tissue of the femur, and sent the specimen to the pathologist for report, which was a sarcoma. The physician who had referred the patient to me felt quite sure that the pathologist was wrong, especially as he had treated him for a chancre nine or ten years ago. So an anti-syphilitic treatment was adopted without any result at the end of a month.

On further study of the *x*-ray I was positive that this suspicious spot in the lower end of the femur was a sarcoma because of its markings; and in consultation with Drs. Coley and Erdmann, it was decided to do an exploratory operation with an amputation if the tumor were found. This was done on the 5th of September, and this broken-down mass was found in the lower end of the femur, the pathologist reporting later that it was a true giant cell sarcoma. The amputation had been made the upper third of the thigh. Dr. Coley undertook the antitoxin treatment with highly gratifying results.

My last report from the patient, on the 25th of July, 1911, was that he was very healthy and there had been no sign of recurrence.

In the *American Journal of Surgery*, May, 1913, Dr. Walter M. Brickner of New York has published a paper the title of which is the following: "The Differential Diagnosis of Syphilis, Tuberculosis, Tumors, and Osteomyelitis of the Long Bones." It is illustrated by *x*-ray prints, which correspond very closely with a large number of plates in my possession.

The text of Dr. Brickner's paper is quite as instructive as the prints, and did time permit I should be glad to quote extensively from this valuable contribution to bone literature. I am reminded, however, gentlemen, that my paper is already too long for an audience in midsummer, but I must be allowed to detain you a while longer with a reference at least to tuberculous knees in the adult, and I could illustrate this branch of the subject by a recital of cases did time permit. Suffice it to say, however, that at the present time a radical treatment, such as excision, is about the best for men and women who are obliged to earn a living. I have in mind a number of instances where excision has served a useful purpose, but the patients have belonged to the better class, have not been obliged to work, and can afford to live in parts of the country where the best air and hygienic measures prevail. It is quite true that cases that are diagnosticated as tuberculous are on what is known as circumstantial evidence. The knees themselves present very few signs, but because there is a history of pulmonary hemorrhage and signs pointing toward invasion of the lung, the tubercular test is regarded by many of my colleagues as a valuable aid in diagnosis; but I have refrained from employing this because I have feared a transfer of the lesion to other parts of the body. I could quote instances where the test has been made by myself and colleagues where other joints were subsequently involved, and inasmuch as the tests made by the average practitioner are not always reliable, I find myself unwilling to employ the same. There are instances where excision of a knee in a tubercular subject has seemed to arrest the disease, especially where the patient has had the benefit of climate and an outdoor life. Take as illustration the following, which, I am sure, would interest the members of this association, as the patient herself spent the early years of her life in Bardstown, Kentucky:

Case XIV. (*No.* 4,049).—On April 29, 1897, a young lady, 18 years of age, sought my advice for a deformity of the left knee dependent upon tuberculous ostitis. When ten years of age she had the first sign of disease in the knee. Symptoms were slow in developing, very obscure. Without going into detail the history is that which we find in the large majority. She was fairly well once the knee was held fixed in an angle of about 150°, a little puffiness on the outer side of the ligamentum patella. She had been through the usual treatment of braces plaster of Paris, etc., and had become thoroughly discouraged.

I did an excision on the 3d of May, 1897, placing the limb in slight hyperextension, as she was short in stature, and I thought that she would be able to walk better. The wounds healed without any suppuration, and on removing the plaster a brace was applied to ensure a better fixation and give her more confidence in the use of the limb.

The further history of the case may be summed up in this way: She became a wageearner, a year or two later serving as reporter on the *New York World;* had a hemorrhage of the lung, and was sent by this newspaper to Arizona, where she spent many months in the saddle, gaining rapidly in flesh and becoming quite active. As she was returning home in 1901, the early part of the year, she attended a dance in Denver, and danced so well that a distinguished surgeon, now deceased, was amazed at her ability to get about so well, and found no lameness whatever. Shortly after this she returned to the city, and I could find no lameness. She has continued well up to the present time. Early in June, 1904, she was married, and has given birth to a healthy child, and has never regretted the operation of excision.

In closing I beg to say that in 11 cases of old tuberculous knees, long since healed, in which I did an arthroplasty, after Dr. Murphy's method, I have been disappointed in the results. (In no single instance has there been enough motion to give the patient satisfactory use of the limb.) Dr. Baer of Johns Hopkins, as you all know, has had some excellent results in an operation which consists in the insertion of a chromicized pig's bladder between the ends of the bones. Many of my colleagues, as well as myself, have done this operation, but our results have not been equal to those reported by Dr. Baer. I do not wish to be understood as criticising these operations; on the contrary, I believe they are perfectly justifiable. These ankylosed joints will ultimately be restored to motion, and we shall all be indebted to the pioneer work of these enthusiastic surgeons.

THE ROLE OF PHYSICAL EXERCISE IN THE OPEN AIR IN THE PROPHYLAXIS OF TUBERCULOSIS.*

By JAMES M. ANDERS, M.D., LL.D.,

PHILADELPHIA, PA.

Systematic physical exercise, as a means of prevention in, and the ultimate cure of, pulmonary tuberculosis has not received that degree of recognition at the hands of the medical profession that its merits warrant. Unquestionably, there has been a disposition on the part of physicians to overlook the signal importance of muscular exercise, since the general acceptance of the principle of rest in the treatment of all cases of this disease in which

*Read before the American Climatological Association at Washington, D. C., May 7, 1913.

fever is present. My object is not to attempt to underrate the great value of rest as a remedial agent in the active stages of pulmonary tuberculosis, but rather to emphasize the first-rate importance of promoting good muscular development as a means of minimizing the number of persons susceptible to this disease.

Efforts to prevent the occurrence of disease were developed to a high standard long before the discovery, through bacteriological research, of the pathogenic organisms of disease, especially by the Greeks and Romans. Later epochs, however, seem to have fallen into an opposite tendency. Among the recognized agencies to keep the body in health and to prevent its germicidal power from running low, an adequate amount of muscular activity is of the utmost importance—more than that, its general adoption would have a vital effect upon the far-reaching future of the American race.

As members of the medical profession, our interest in the national physique and the evenly balanced condition of mind and body of the American race, not only during school life, but also during later life, should be greater than that of any other class of society. The question may well be asked in all seriousness: Whether the medical profession has lived up to its reasonable responsibilities with regard to the tendencies to push the head at the expense of the muscles and sinews both at school and at the university, and to retire from one's business career a physical bankrupt at or before fifty years of age?

It is an indisputable fact that the American race, as a whole, is slowly undergoing muscular deterioration, of which one of the principal causes is insufficient physical exercise out of doors, or, in other words, our mode of living as a nation. Two additional considerations to be reckoned with in accounting for our lack of physical stamina are the ingestion of physically inferior races from abroad and the undoubted trend away from occupations requiring the use of the voluntary muscles. It is difficult to understand the lack of interest by the medical profession in the opportunity opened by this state of affairs to point out to educators the supreme importance of keeping the body strong and healthy as the prime requisite in racial supremacy.

It is an accepted principle that increased respiratory exchange, the result of muscular activity, improves the metabolic processes and general health of the body. It must be recollected, therefore, that the endurance or resistance of an individual is in direct relation to his muscle power or muscular development, which, it has been well said, means his "physical development."

Of special interest to this Association is the fact that climate also exercises an influence of some moment upon the standard of physical efficiency. For example, in general terms, the muscular development of people residing in cold or temperate climates is better than that of those residing in warm climates. True, the latter take less bodily exercise, "but this is offset by taking less food, augmented skin action, and, therefore, increased circulation." Moreover, the physical development of "people living in the interior is better than that of those living on the coast, and in the mountains better than in the interior. People in the interior are usually farmers whose occupation necessitates an outdoor life and the use of the muscles; the reason for the hardiness of the people in the mountains is, of course, apparent."* The struggle for prevention in tuberculosis and other infective diseases can be, in the present state of our knowledge, carried on both intelligently and effectively by directing efforts primarily to the specific cause, including the prevention of infection, and by the removal of favoring conditions and predisposing causes connected with the individual. In the case of pulmonary tuberculosis, the specific cause rarely becomes operative unless predisposition exists.

From the standpoint of both prevention and cure in pulmonary tuberculosis, our most effective means are those that enable the human organism to resist the infection. We cannot annul the tubercle bacillus by a direct attack, although there are known means to prevent exposure to infection, and these are to be advised and encouraged. Unless it be found practicable to permanently immunize human beings by the inoculation of non-virulent living tubercle bacilli, then efforts to raise the standard of physical efficiency to the point of establishing natural immunity may not be relaxed.

Movements to prevent tuberculosis must also include the isolation and institutional treatment everywhere of advanced tuberculosis cases. The departments of health officials should be educational forces in the community, instructing the people among other things in the principles and details of the prevention of tuberculosis. Educational work of this character should begin among the children of both sexes in our public schools.

In dealing with the problem of the prevention of disease, the individual is regarded as the unit of a mass, but in the case of tuberculosis we can deal with human beings as individuals, and by selecting persons markedly predisposed to this dread disease enable them to bring about a condition of immunity as the result of systematic physical exercise and other measures. Obviously, the prevention of tuberculosis involves something more than physical exercise persistently carried out, but its commanding position in accomplishing a state of physical development that successfully resists this dread disease is undoubted. The fact, as the Germans put it, that "every one is a little bit tuberculous," goes to show how easily the disease is preventable. Says Ritchie,† pertinently: "If the American people would use one-half the sum that tuberculosis is costing them each year, in fighting the disease, it is probable that tuberculosis would soon cease to exist."

There are certain well recognized local predisposing conditions, such as the paralytic thorax, anemia of the lung-texture, collapsed air cells, all of which can be overcome successfully by suitable exercises, and thus lung resistance increased. Says Ingals‡ in a paper read before this Association on the same subject as that of the present discussion: "One of the most common observations made by medical men is that the long, narrow, flat-chested individual is the one who is most liable to the development of tuberculosis; and we have all observed that in patients presenting this form of chest the chances for recovery are reduced to a minimum. This single observation is sufficient to suggest that systematic physical training, which would develop the respiratory muscles, expand the thoracic walls

*"Muscular Development, the Causes for the Lack of It, and the Value of Physical Exercise," *Journal American Medical Association*, March 9, 1912.

†"Primer of Sanitation," by John W. Ritchie, p. 175.

‡Transactions of the American Climatological Association, 1898, Vol. XIV.

and correspondingl increase the pulmonary capacity, would be of great service, not only in preventing tuberculosis but in curing its early stages."

The true significance of systematic physical exercise and deep breathing for their effects in increasing the vital power and resistance of the lung-texture has not been given due prominence by the profession. From the personal results obtained, I feel strongly that a growing tendency on the part of the medical profession to make trial of this suggestion would soon lead to its more general adoption.

The rationale of the physiological effects of muscular exercise and deep breathing is easily comprehensible, for thus are obtained exhibitions of greater distention of the air-cells, improved circulation of the blood through the lungs whereby the localized anemia is removed; in other words, there is brought about an improved metabolism and a greater resistance of the lung-texture. To show the beneficial effects of appropriate breathing, I quote again from Ingals' excellent article: "One of the first injunctions we should place upon the patient who has any reason to anticipate the development of pulmonary tuberculosis is that he should expand the lungs thoroughly several times every day.

We must also personally inspect his mode of breathing, to see that he knows how to carry out our instructions. In order to expand the lungs the patient should be directed to draw in the abdominal walls and take a long, deep breath, while the shoulders are carried gradually backward and the ribs and sternum elevated as far as possible; he should hold his breath for a few seconds and then blow it out slowly and forcibly through a small opening between the lips. In this way not only the air-cells which can be reached by direct inspiration are inflated, but also those at the apices and along the borders of the lungs, which otherwise might not be distended."

Equally important for its effects upon the respiratory system is general muscular exercise. It must be taken systematically and for the most part out in the open, as well as wisely prescribed and regulated, in order to be rendered effective. At the outset of this aspect of my subject, I wish to disclaim all responsibility for the encouragement which has been given to professional athletics in recent times. On the other hand, it seems to me that professional interest should, without difficulty, be aroused to a vigorous discussion of the possibilities of muscular development with a view to securing a high standard of physical efficiency. To this end the proper use of the muscles easily shares first honors with diet and fresh air, but the former factor has received less professional attention than the two latter.

It is probable that in the presence of the local conditions mentioned above, *e.g.* paralytic thorax, pulmonary anemia, an implantation of tubercle bacilli may have already taken place, so that an accurate diagnosis should be attempted in all suspects by modern methods, but even though incipient tuberculosis is recognized, carefully supervised physical exercise is to be advised and encouraged whenever the maximum daily temperature is not above 99.3° F. and the effects noted.

In explanation of the beneficial effects of muscular exercise a few familiar principles may be enumerated: (*a*) The process of disintegration of muscular tissue is hastened by physical activity, and hence renewal or repair is to a corresponding degree stimulated, provided that sufficient rest be allowed during the intervals. (*b*) It is a physiological law that the working power and resistance of the individual are within certain limits, at all events, in direct relation to the activity of the metabolic processes; and muscular activity particularly active outdoor exercise, is the principal factor in promoting these wholesome tissue changes. (*c*) It is to be recollected that not only the muscles themselves are benefited in carying on an "internal respiratory" function, in which the ultimate exchange of oxygen and carbon dioxide takes place in the muscles, but by their action they also stimulate the circulation, both general and pulmonary, thus aiding in the elimination of the products of combustion, superfluous heat, etc. (*d*) Muscular activity brings into more active play all of the viscera; the appetite and digestion are improved while the circulation of the blood, the brain and nervous system are invigorated. (*e*) Of special interest as bearing upon the subject under discussion is the fact that "increased muscular activity means increased respiratory efforts, since there is greater oxidation and, therefore, a greater loss of carbon dioxide and a consequently greater demand for oxygen. It is this increased respiratory exchange in muscular activity which increases the nutrition and general health of the body." (Friedman.)

If it be true that the human body can resist an implantation of the tubercle bacillus when in a state of good physical development or healthy nutrition, then obviously muscular exercise in the open air holds forth promise of great usefulness, since favoring conditions and predisposing causes of this disease may thus be overcome. I need not revert to the muscular exercise most suitable to bring about a healthy condition of the system. It should ever be recollected, however, that these will depend upon the occupation, period of life, and strength of the individual, at the start. For example, the work in which individuals are engaged being greatly varied, calling into action now one set of muscles and nerves and now another, it follows that the recreation exercises must be similarly varied in order to bring into play those portions of the body that usually remain inactive during the ordinary avocations of life.

The amount of general muscular exercise necessary to the accomplishment and maintenance of sound health required by a man of average height and weight in the prime of life is equivalent to a daily walk of six miles on a level path, while growing lads and women, who are rated as equal to lads of sixteen, require somewhat less. Obviously, this daily quantum of exercise is needed by those whose employment is principally sedentary. On the other hand, an active outdoor life may diminish the six miles' walk quite considerably. It follows from the foregoing facts that the details connected with the regulation of the muscular exercise will vary with the individual.

In conclusion, I believe that well regulated physical exercise is one of the strongest safeguards that we have for the maintenance of a national physique that is vital to the successful prevention of tuberculosis. Lastly, I am ready to join with those who try to limit the abuses incident to competitive sports and training.

1605 Walnut Street.

LIQUOR LEGISLATION AND INSANITY.*

By EDWARD HUNTINGTON WILLIAMS, M.D.,

MONTCLAIR, N. J.

FORMERLY OF THE NEW YORK STATE HOSPITAL SERVICE

DURING the past year the statement has appeared repeatedly in print that prohibition is directly responsible for the decrease of insanity in Kansas. Certain publications have asserted, indeed, that Kansas is the *only* State in which insanity is actually decreasing. If either of these statements be true the fact is of great significance. For in the United States as a whole insanity seems to be steadily increasing.

It is a well-known fact that such thickly populated States as Massachusetts and New York have a higher percentage of insanity per capita than the group of rural States extending northward from Oklahoma to the Canadian line. But obviously this fact does not prove that Western legislation is superior.

We are not justified in assuming, for example, simply because the "wet" State New York has more insane persons per capita than Kansas, that prohibition is responsible for this difference. Yet this comparison has been used repeatedly as an argument in favor of prohibitive liquor legislation.

Any comparison to be convincing must be made between States closely similar in every particular. Kansas and Nebraska present such similarity in a more striking degree than almost any other two States in the Union. They are closely similar in size and shape and in the geographical distribution of the population, each State having a relatively thickly settled eastern half, while the western half is sparsely settled. They have practically the same percentage of native whites, negroes, foreign-born whites, ratio of males to females, percentage of illiterates, percentage of urban population, and percentage of increase in rural population. Neither State has any large city, and their gain in general population during the census period was practically the same, Kansas gaining 15 per cent., while Nebraska gained 11.

Obviously, then, they are strikingly similar in every important particular except in methods of controlling liquor traffic. Let us see what a comparison between their insane populations will show. According to the statistics issued recently by the Census Bureau the number of cases of insanity committed per 100,000 population in Kansas decreased from 62.2 in 1904 to 52.4 in 1910. Meanwhile in Nebraska there was a decrease from 62.1 (practically the same as Kansas) in 1904, to 34.5 per 100,000 in 1910. Moreover, there were fewer cases of insanity present in the Nebraska institutions than in those of Kansas at the close of the period, Nebraska having only 143.9, while Kansas had 165.6 for each 100,000 population.

It is evident, therefore, that Kansas is not the only State in which insanity is decreasing. It is not even the State in which there has been the *greatest* decrease, this last honor going to its neighbor, Nebraska. From all of which it is evident that Kansas's insanity record furnishes no basis for claiming superiority of the prohibitive form of liquor legislation.

However, in the case of such a complex problem as the relation of liquor legislation to insanity, we should hesitate to accept as conclusive evidence any single set of statistics lacking definite corroboration along other lines. Fortunately in this instance we have such evidence in the index given by the alcoholic psychoses.

It is understood, of course, that the excessive use of alcohol may affect the mentality without producing alcoholic insanity, and that indirectly it may be a factor in producing certain forms of insanity without the usual manifestations of alcoholism. But the forms of insanity included in the well-defined group known as the alcoholic psychoses are the direct result of the use of alcohol.

It is apparent, therefore, that the number of cases of alcoholic insanity committed to the institutions of similar communities, will give a fairly accurate index to the relative amount of alcohol consumed. If prohibition is really effective, as claimed, such States as Kansas and North Dakota should have no alcoholic insanity, or, at worst, should make a far better showing than the license States, Nebraska and South Dakota. What the records really show is as follows:

In the North Dakota hospital for the insane a little less than 4 per cent. of the patients admitted in 1910 had alcoholic insanity. In South Dakota the percentage of this form of insanity was just over one per cent. in 1912. In the Nebraska hospitals the average percentage of alcoholic psychoses admitted last year was a little over 4 per cent. Meanwhile the Kansas hospitals admitted 5 per cent. of this form of insanity during the same period.*

Thus Kansas heads the list in high percentage of alcoholic insanity, with South Dakota trailing so far behind as to make the prohibition State seem like a veritable den of tipplers by comparison.

But perhaps the most significant thing shown by a study of the records is the fact that Kansas had an actual *increase* in the alcoholic psychoses during the last three years—at the very time when prohibition was "being more rigidly enforced than ever before."

There is another index to the relative consumption of spirituous liquors which may very properly be considered. This is the percentage of cases of paresis to the total insane population. We know, of course, that syphilis, not alcohol, is probably the direct cause of the disease. But this does not alter the long-known fact that alcoholism and venereal diseases are usually concomitant conditions. Indeed, there are eminent psychiatrists who maintain that alcohol is at least indirectly productive of paresis, judging from the prevalence of paresis in communities addicted to alcoholic excesses.

We should expect, therefore, that in communities where there is a high rate of alcoholic insanity there will be a high percentage of paresis, and vice versa. It is not an absolute index in either case, of course, but an examination of the records of a large number of institutions show that this evidence is at least strongly confirmatory.

We should expect to find, for example, in the Manhattan State Hospital, which draws its patients from New York City and has a high percentage of

*Presenting some features of an investigation recently undertaken for the MEDICAL RECORD.

*This is the figure given by an officer of the Kansas State Hospital service after a careful study of the subject. The printed reports give this percentage as slightly lower, but the officer's estimate is probably correct. In several other instances I have been greatly aided by personal reports made by staff members, and these reports are particularly valuable, since in several institutions the printed classification of patients is wholly inadequate.

alcoholic psychoses, a far higher percentage of paresis than in the rural State of Iowa. And we do actually find that during the last five years there has been an average percentage of about .12 of paresis to .09 of alcoholic psychoses in the Manhattan hospital, as against .06 of paresis to about .05 of alcoholic insanity in Iowa during that period.

It is significant, therefore, to find that North Dakota in 1910 had about 2 per cent. cases of paresis to about 4 per cent. alcoholic psychoses; South Dakota, paresis about 2 per cent. to alcoholic psychoses one per cent. in 1912; Nebraska, paresis a little over 6 per cent. to alcoholic psychoses something over 4 per cent., and in the Topeka hospital, which I am assured by its officers is representative of the State, the paresis 8 per cent. to alcoholic psychoses 5 per cent.

Here again, then, Kansas leads her group of States in high percentage—completely overshadows them in paretic population. Moreover, just as in the case of alcoholic psychoses, the records show a steady increase of paresis in Kansas during the same period in which there has been a fairly uniform decline of this disease in each of the other States except Nebraska. Yet even in Nebraska the percentage of paresis to the total insane population is far less than in Kansas.

It is evident, therefore, on the basis of Government statistics showing the decrease of insanity in the different States, and the records of the various State hospitals as to the relative number of cases of alcoholic insanity and paresis, that there is no justification for the claim that Kansas' "prohibitive" form of legislation lessens the amount of insanity.

On the contrary the facts seem to substantiate the claims of the license advocates that in prohibition States the relative consumption of spirituous liquors is increased, and the amount of malt beverages diminished. For whiskey, not beer, is the cause of most alcoholic psychoses.

It has been suggested that the relatively small number of insane in this group of Western States "may be simply an evidence of how poorly these unfortunates are cared for." But such a suggestion is entirely unwarranted. The Western hospitals for the insane, individually and collectively, make as good a showing in every particular as any group of similar institutions in the East.

The work done in the State Hospital for the Insane at Topeka, for example, and the hospital itself, compares favorably with any of the New York institutions. The superintendent, Dr. T. C. Biddle, a veteran in psychiatry, is a man of progressive ideas and unusual executive ability. In addition, he has the rare faculty of "putting the right man in the right place," as illustrated by the work done by the members of his staff.

The hospital itself affords opportunity for the most advanced methods of studying and treating insanity. The new Psychopathic Hospital, completed last year, is one of the best in the country. It is the result of Dr. Biddle's long and careful personal studies of similar institutions, East and West, and represents a combination of all their good qualities. Its equipment is complete, and the methods of observing and recording cases are thorough and systematic.

The laws governing the commitment and care of the insane in Kansas, while unfortunate in some respects, are good as a whole and growing progressively better, thanks to the efforts of such men as Dr. Biddle and Mr. Harry C. Bowman of the Board of Control.

Mr. Bowman has recently prepared a bill providing for the examination and treatment of voluntary patients at the State hospitals that might well be copied by our Eastern States. The effect of this bill will be to bring the members of the hospital staffs in contact with cases of incipient insanity at the time when preventive measures may be effective, and before the disease has reached a stage necessitating commitment. This will be a noteworthy step in practical mental hygiene.

I mention these things as illustrating how keenly alive Kansas is to the importance of properly caring for the insane. And Kansas is no more so than Nebraska, or the Dakotas. So that the suggestion that the low insanity rate is due to ignorance or indifference may be discarded.

The real explanation seems to be that the people and their surrounding conditions are different from those in the East—a higher type of people on the average, with much better surroundings. Most of them are native Americans, and, as compared with the East, live in comfortable circumstances. Great wealth and distressing poverty are unusual conditions there, and the average general intelligence is much higher than in most Eastern States.

This last fact is shown conspicuously in the character of the inmates of Western insane hospitals, who present a striking contrast to the inmates of the New York or Massachusetts hospitals. The degraded, disgusting types that are the product of city slums are wanting; and the class of ignorant foreigners that congests our metropolitan hospitals is practically unknown.

So we are justified in believing that Kansas and her sister States should thank general conditions, rather than any special form of liquor legislation, for their relatively small insane populations.

12 Melrose Place.

DIET SOCIAL SERVICE IN DISPENSARY WORK.*

By FRED H. KLAER, M.D.,

PHILADELPHIA, PA.

PHYSICIAN IN CHARGE MEDICAL DISPENSARY, HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA; INSTRUCTOR IN MEDICINE, UNIVERSITY OF PENNSYLVANIA.

The importance of diet instruction in the treatment of disease is well recognized, especially in private practice, where it has been fairly well carried out. This has not been so true, however, in the treatment of the ills of patients in dispensary practice, in whom the need for such help and instruction is even greater than in the case of patients in the better walks of life. The reasons for this are manifold, but the one of greatest weight has been the difficulty of giving this instruction in a practical way. Now, however, with the help of the Social Service, we have the ways and means of bringing this method of treatment to the patient in a way which will be not only intelligible, but most practical and useful.

About two years ago, impressed with the poor results we were obtaining in patients with the various forms of gastrointestinal disorders in the Medical Dispensary of the Hospital of the University of Pennsylvania, I tried the experiment of referring all of these patients to the Social Service for instruction and supervision along diet lines. My sis-

*From the Medical Dispensary and Social Service Department, Hospital of the University of Pennsylvania.

ter, Miss Edna M. Klaer, at the time a teacher of dietetics in the public schools of Philadelphia, was persuaded to give volunteer services for a few hours each week to supervise this work. After a short period the work was interrupted, but had given such good results that in September, 1912, Miss Klaer was definitely engaged through the Social Service of the Outpatient Department of the hospital to give four hours a week to looking after the diet cases in the dispensary. The report given below is a summary of the results obtained for the period from September, 1912, to June, 1913.

While many of the patients are referred to as special diet cases, the diet prescribed in the majority of them was a simple mixed general diet. As soon as a diagnosis was determined the patient was referred to the dietitian with a note giving the diagnosis and the type of diet desired. Of course, proper medical and hygienic measures were being carried out at the same time. In many of the cases, however, treatment other than special detailed diet instruction had been in progress for weeks or months without giving satisfactory results. The majority of the patients represent the various types of digestive disturbances—gastric neuroses of various grades and types, especially that associated with hyperchlorhydria, gastroptosis, gastrectasis, a few cases of gastric ulcer, and one of chronic appendicitis, with pyloric stenosis awaiting operation. There were also a few patients representing the various types of metabolic disorders: arthritis, nephritis, and diabetes. Most interesting of all was our study of a number of families, where for one reason or another we were led to believe that dietetic errors were at the basis of the poor health of several members of the family.

In general the patients fall into two groups:

(a) Individual patients suffering with various digestive disturbances or diseases requiring special diets.

(b) Families requiring a readjustment of finances, food, and habits of eating, because of debts, malnutrition, and sickness.

When the patient is first referred to the dietitian an attempt is made to get some general idea of home conditions and surroundings, the kinds and amounts of food, methods of preparation, and regularity of meals. The meals of these patients usually consist of fried foods, meat, potatoes, and bread, often taken very irregularly and washed down with large quantities of tea or coffee.

After getting this general information, the patient is advised as to the best foods for his condition. In this special emphasis is laid on cereals properly prepared, bread or toast with butter, vegetables in various combinations, fruits cooked or raw, eggs, moderate amounts of meat, but so prepared as to improve its digestibility, and milk in the form of thickened soups or purées, sauces or dressings for vegetables, or in desserts. Special instruction also is given in regard to water drinking. In some cases recipes for cooking the food are given at the first visit; in others these are withheld until later.

These recipes consist of printed methods for cooking the common foods, such as cereals, vegetables, fruits, and cheap cuts of meat. Before the close of the first interview the patient is asked to keep a written memorandum of the foods eaten during the time intervening before the next visit to the hospital.

The first interview is usually at the hospital. The second, if possible, at the home to confirm the data obtained, and to judge from the condition of the home whether directions can be carried out.

In the cases of working girls or of married men referred for diet, the home must be visited to give instructions to the mother or wife, as the latter seldom appreciates the need for diet or understands the kind of diet required without a special interview.

In some cases it has been necessary to give actual cooking instructions as well as recipes. After the home has been visited once the patients are interviewed at the hospital, although more definite results might have been obtained in certain cases if the home could have been visited more often, and the patients more closely followed up.

In the cases in which the patient did not return to the dietitian for further instruction a letter was sent asking the patient to report. This sometimes resulted in a continuation of visits. The cases in which no answer was received from the patient were closed.

There were 50 special patients and 16 families, including in all considerably over 100 patients directly under study and supervision. Of the 50 special patients referred during the nine months, 10 patients have not returned regularly or have been seen only once or twice and have not answered letters sent them. With the dietitian on full time many of these patients could have been better followed up and kept under supervision. Seven patients have been referred so recently that nothing definite can be determined as to the results of instruction. Five others were patients with gastric ulcer, three of whom are to be operated on. In these five, however, despite the condition, some degree of improvement has been brought about by following the diet prescribed. The remaining 28 patients show definite improvement, most of them now being on a general diet and reporting only occasionally to the doctor or the dietitian.

All of these have been relieved of the symptoms which brought them to the dispensary. Many of them have gained in weight and are working full time. In some chronic indigestion had been present for many months and was unrelieved by private or dispensary physicians, who relied especially on drugs; these patients often showed prompt improvement with a readjustment of diet and instruction as to the proper preparation of food. Many of these patients have stopped coming to the dispensary, and when recently visited were found to be in good health and following the instruction given them.

In some of these patients, however, there was a tendency to relapse. This usually occurred where for one reason or another they had gone back to their old habits of eating. This emphasizes the need in the case of these special diet patients for cooperation with the home, and is well illustrated in three cases. The patients returned to the physician and dietitian after an absence of three to five months because feeling so well that they began to eat what the family had for meals, with the result that they again became ill. One of them, Mary S., was sent for diet because of anemia, gastroptosis, and acne. She had been eating very irregularly, much of her food being candy or ice-cream. She was given a strict diet, which she followed very carefully and on which she began to improve. The kinds of food were gradually increased until she was eating a general nourishing diet. Then she went back to work and stopped coming to

the hospital. In four months she returned, after having adopted the habits of her family again, unable to retain food eaten, and the same course of dieting had to be started all over again. William B. was referred for hyperchlorhydria on November 6. He followed directions very carefully, improving so much that by December 20 he was on a general diet and was not to return to the hospital again unless he became ill. In about three months he returned because he had had a recurrence of the trouble, due, he said, to eating the food the rest of his family were eating. George W. was also referred for hypochlorhydria on October 30. He was a travelling salesman, who, after three visits to the dietitian, went out of the city for a time. Before leaving he was put on a general diet, which he followed carefully for five months, during which time he gained 16 pounds in weight. May 19 he came in to see the physician in regard to a stomach upset following his return to home conditions. All of these relapses might have been prevented if the instruction could have been carried beyond the patient to the home.

Diet work for the individual is not broad enough. To be very effective and lasting corrections of the home conditions must be made to prevent the patient returning to the habits which caused his original trouble. These corrections can only be made by spending more time in visiting the homes and trying to change the habits of the family as well as those of the individual. Another reason why special diet cases should become family readjustment cases is because it is usually found that the same digestive trouble which brought one patient to the hospital is present to a greater or less degree in all the members of the family. It is usually only a matter of time before other members of the family will need treatment of one kind or another.

The necessity of giving a patient (1) proper food properly prepared, (2) more nourishing food for the money spent, (3) relief from indebtedness, is the basis of the family readjustment attempted in sixteen families.

Some of these families were referred by the Children's Dispensary because of chronic digestive disorders in several of the children of the family. The physicians found that their advice about kinds of food necessary for the patient could not be carried out because of either the cost of the food or ignorance in the matter of preparation. Of these sixteen families five were in the care of two volunteers who accomplished very little because of insufficient training for the work and lack of adaptability to conditions.

The other eleven families were handled by the dietitian and three volunteers. The dietitian, although paid for only four hours weekly, really spent more than this, owing to her interest in the work. The volunteers were each able to give only one-half day's work every two weeks.

In six of these families there has been very definite improvement, not only in the physical condition of the families, but also in lowered cost of living. The families are having better planned, better cooked, and more nourishing meals, expenses are lower, and in four families outstanding bills have been paid in part or in full. One family has paid a debt of $42, and is now paying cash for food instead of charging.

Another family—father, mother, and eight children, the oldest a girl of 15 years—is earning about $80 monthly. December 1 they owed a debt of $161 at a corner grocery, where they paid one to five cents more than they would have paid in cash for the same article at a cut price store. Besides the grocery debt, they owed $50 milk bill, $15 loan to a neighbor, $44 butter and egg bill, besides other small bills amounting in all to about $25. In order to try the experiment of saving money by paying cash, $35 was advanced by the Social Service for groceries. This advancement enabled them to start out the month without last month's grocery bill to pay. After instruction it was also found that $7 weekly gave the family better meals than they had had before for $8 or $9. Since January 1 the family has paid cash for all food besides paying an average of $12 monthly on debts. The grocery bill is now $118, the neighbor's loan of $15 is paid, besides a small amount on all other debts. The loan of the Social Service Department will be paid last. The physician reports that the family as a whole are in very much better condition physically than they were last year at this time. The father has drawn full wages for two months. Up to January 1 he usually was ill from six to twelve days monthly. The family now have something to work for; their ambition at present is to have the grocery bill paid off by next year at this time. Intensive work has been done in this family under very favorable conditions, but also with the drawbacks of large debts, the charging habit, and ill health. The good accomplished here shows the need, which is found in many other families, of systematic keeping of household accounts, careful planning for meals and necessary expenses, an occasional loan, until the family is on a better basis, to prevent the beginning of charge accounts at food stores, a little encouragement and help in solving the problem of how to make money serve its full value to furnish healthful nourishing foods.

Of the five unsuccessful families out of the eleven, two showed only slight improvement, one was unsuccessful because of poor co-operation, and the other two were given up as readjustment cases because of chronic illness, which in one case affected the supply of money and in the other prevented the mother from making the necessary effort.

In the six successful cases, after the confidence of the family was gained, the mother was encouraged to keep an itemized account of meals and bills from week to week. Corrections were made by the dietitian and suggestions given as to cheaper, more nourishing foods.

The following are the most common corrections:

1. Use of skimmed milk (5 cents per quart) for cooking.

2. Use of stale bread, two loaves for 5 cents, instead of 5 cents a loaf.

3. Cereal in bulk rather than in package. Oatmeal in package, 10 cents. By bulk same amount costs from 5 cents to 6 cents.

4. Coal by half ton instead of by bucket. One family used 30 cents worth of bucket coal daily, costing $8.40 a month. After instruction half a ton at $2.75 lasted the same length of time.

5. Paying cash for food at cut-price stores, instead of buying on a book at the corner grocery. One family saves $1 to $1.50 weekly in this way.

6. Housekeeper going herself to buy perishable foods, such as fruit, vegetables, and meat. In one family a small girl of 10 years is usually sent for supplies. One day she was given tainted meat;

another time she was given 1¾ pounds of meat when she asked for a pound. Again she received small, gnarly apples for the same price that was charged for good ones.

7. Watch bargains at cut-price stores; branches of the large retail stores sell, for example, 3 cans of vegetables for 25 cents, ordinarily 10 cents to 12 cents a can. It is possible for them to do this partly because they do not deliver goods, and the discount on the large quantities bought at the center enables them to undersell small retail stores.

8. Use of butterine at 25 cents and 30 cents a pound as substitute for butter at 40 cents or even 50 cents per pound in winter. Cheap butter is usually made of material not so pure as a good quality of butterine.

9. Use of properly cooked cheese as source of cheap protein. When used with other foods, such as macaroni, potatoes, rice, etc., or in soup, it is quite digestible, provided it is melted, but not boiled.

10. Use of cream vegetable soup for lunch for school children, who need more milk daily and more mineral, which can be obtained in vegetables and milk, and a hot nourishing lunch in order to do their best work in school.

11. Use of cheap cuts of meat cooked a long time in brown gravy, or potroast, etc. Much more nourishing than frying the same for 10 or 15 minutes.

12. The drinking of more water, which in all patients has been a definite factor in improving conditions.

All the mothers were given the printed recipes, and in some cases the use of these was taught in actual cooking lessons in the home, using their own equipment to overcome the objection that they have not the utensils to work with. There is found very often a prejudice against certain cheap foods which is sometimes overcome by careful preparation by the dietitian. Cooking lessons are especially necessary for foreigners who cannot read English and who do not know the kinds or the ways of preparing American foods.

In these six families showing definite improvement there are 47 members being benefited by improved conditions. Many of the suggestions given have been carried to the neighbors, so that the field of improvement has spread beyond the single patient or family.

There is found in the special diet cases, as well as in the family readjustment cases, an amazing ignorance of the common methods of cooking and the economical purchase of nourishing foods. If cereal is used it is seldom cooked more than one-half hour. Vegetables, except cabbage and potatoes, are said to be too expensive and usually not liked especially by children, who need them the most. Meat is fried or boiled, and considered absolutely necessary to furnish strength to do work. In these cases some of their digestive disturbances can be improved very much by substituting the carbohydrate foods for meat. Many patients are troubled with constipation, yet fruit is scarcely used except bananas, which are almost always eaten green, or oranges, which are too expensive. The use of dried fruits, cooked apples, figs, dates, etc., is almost unknown.

The improvement noted in the special diet patients and the family readjustment cases, with the small amount of time spent on them during the past nine months fully demonstrates the need and advantages of this work in connection with medical dispensary work. Diet instruction and supervision through the agency of the Social Service will not only save time for the physician, but will accomplish results in the patients which at least thus far in dispensary work have not been obtained. It will shorten the time of treatment in the dispensary and start habits which will not only cure the disease which brings the patient to the dispensary but also prevent its recurrence. In other words, this work starts at the foundation and source of many ills, the removal of which will give us better nourished, better developed, and more healthy citizens, and will help to solve many of the problems arising from poverty and disease.

POSTOPERATIVE INTESTINAL STASIS AND THE INTRAABDOMINAL USE OF OIL.*

By WATERS F. BURROWS, M.D.,

NEW YORK.

Since my subject has reference to a postoperative abnormality, it is interesting to note that much has been accomplished in hastening convalescence and eliminating the discomforts and complications of the surgical patient by permitting early postoperative freedom of movement and through placing of the patient in the partial or complete sitting posture after the administration of the general anesthetic. The abdominal case operated upon without delay, returned to a bed raised eighteen to twenty-four inches at the head, permitted to move from side to side and sit upright in bed upon the second or third day, convalesces rapidly and, more important, avoids such complications as embolism, thrombosis, pneumonia, and difficult micturition with its dangers of cystitis. Intestinal functioning is likewise bettered, there is less inhibition of peristalsis and evacuations occur sooner; yet frequently intestinal disturbance is shown by a coated tongue, loss of appetite, abdominal distention and pain, while excessive vomiting and inability to easily pass gas or bowel contents by rectum emphasizes the fact that there are other important considerations.

Referring, in this communication, not to the cases with more or less complete inhibition of intestinal peristaltic activity, such as is present in advanced peritonitis, nor to those where there exists an obstruction, dependent upon adhesions, kinks, exudates, rupture of the operative wound, or accidental constrictions of the gut caused at operation, but to the more common ones, with less interference with the fecal current, seen after many abdominal surgical procedures, it is evident that the last are associated with a regional or segmental gut spasm. There is present a form of intestinal obstruction accompanied by its usual signs, vomiting, some abdominal distention, and inability to readily pass bowel matter and gas. The bile-stained, continued, and often excessive vomiting is not fully accounted for by the gastritis resulting from the anesthetic. Comparative rarity of true fecal vomiting indicates the evanescence of the obstruction, which seldom exists long enough or to the extent necessary to cause regurgitation from the ileal loops. Fecal vomiting, however, does occur in this condition, may be mis-

*Read before the Surgical Section of the XVIIth International Congress of Medicine, London, England, August, 1913.

taken for acute gastric dilatation, and overcome without the necessity of secondary operation, required when some mechanical etiological factor is present. Acute abdominal pain develops, dependent upon intestinal spasm and edema, while, proximal to the gut involved, increased peristalsis occurs. Accumulation of gas follows when obstruction is unrelieved or spreading peritonitis is present and meteorism may become extreme, indicating overdistention and relaxation of the intestinal musculature, and a congested, sluggish circulation, conditions favorable to the spread of intraabdominal inflammation. Pain then becomes much decreased on account of the septic condition which supervenes and from discontinuance of muscular spasm. In its place there is the distress which results from encroachment of abdominal viscera and diaphragm upon the thoracic cavity, breathing becomes more difficult, and interference with heart action increases its irregularity and adds to the abdominal vascular disturbance. Associated with the condition there is always more or less irregular peristalsis, distention, and incomplete evacuation of the colon and rectum, which to some extent explains the beneficial results of an effectual stimulating enema. However, the expulsion of gas, following a rectal irrigation, is not in itself as important as the reflex, activating effects which a successful colonic stimulation exerts upon the rest of the intestinal tract, causing a return to normal, uninterrupted, wavelike peristaltic contractions.

The small intestine is usually the site of the abnormality as is shown by the diffuse character of the pain and distention, when present, which is not typically colonic. With distention of the colon pain is never so severe or only becomes so when, with obstruction, the small bowel distends secondarily, it is more definitely located, either in the sigmoid, most frequently, cecum or other portion, and the "ballooning" is most marked in the transverse colon above the level of the umbilicus. Moreover, that the small bowel, not the large, is principally involved, is clinically demonstrated by the frequency of serious, excessive vomiting and severe abdominal pain following operative procedures upon the small intestines or in the upper abdomen, where they are more exposed to irritation during operation than in either pelvic or iliac regions. In the lower animals, the dog in particular, the small gut contracts violently and becomes a stiffened, spastic tube upon even moderate irritation, whereas the rectum and large bowel are less perceptibly affected.

During the early stage of postoperative intestinal stasis the prognosis for spontaneous return of normal peristalsis is good, relief is affordable, and suitable measures favor the propulsion and evacuation of intestinal contents, but with the advent of distention, following a primary period of spasm and pain, the condition present has, almost without exception, passed what might be termed an exaggerated physiological stage, has become complicated and demands secondary operation. In the aged, following operations where large intraabdominal growths have been removed, or where a relaxed belly wall exists, there may occur, in the absence of actual obstruction, a degree of distention postoperatively which is not usual. In these instances there is the distress caused by pressure upon the respiratory and circulatory organs in the thorax but absence of severe abdominal pain. The condition is one of intestinal atony, associated with deficient intraabdominal pressure, the danger is less, and with stimulation, especially the use of strychnine, atropine, enemata, and extraabdominal pressure intestinal activity is regained.

The treatment of intestinal stasis and spasm consists in resorting to rectal enemata, containing soap, turpentine, alum, castor oil, glycerin, magnesium sulphate, etc., in combination or singly, or the use of large, continuous, saline rectal irrigations, with or without essence of peppermint added. Strychnine aids the weakened patient; atropine, in large doses, inhibits abnormal spasticity; turpentine stupes and mustard pastes applied to the abdomen reflexly favor return of normal peristalsis, and the rectal tube left in place for the escape of gas, and stomach lavage may both be effectual. Eserine, theoretically contraindicated, is often used to overcome an intestinal atony, erroneously believed present, while "hormonal" acting similarly and more powerfully upon a bowel already in spasm, is consequently additionally distressing and ineffectual in producing results in the worse cases. Attempts through enterotomy to empty the gut of its contents, with failure to eliminate the cause of obstruction, is attended with almost universal disaster. The position of the patient, lying upon the side, especially the right, is often a means of affording relief, and the partial sitting posture, drinking of fluids, and early taking of solid food conserve energy and hasten recovery. Morphine is indicated in many instances, not only controlling pain but, through relaxing the spastic gut, aids intestinal propulsion.

The pain disturbance and actual dangers resulting from postoperative bowel stasis makes evident the importance of prophylaxis. Not only are the means used to remedy the condition largely symptomatic and only partially effective, but some of them are in themselves attended with discomfort and often repeated procedures, each adding to the patient's fatigue, are required before a normal condition is restored. All attempts at prophylaxis depend upon recognition of the causes of postoperative intestinal stasis and these may be classified as follows:

1. Irritation of the intestinal musculature or peritoneum resulting in spasm and obstruction at the site of excitation, with consequent increased peristalsis and accumulation of intestinal contents proximally and a reflex contraction at other susceptible portions of the alimentary canal.

2. A secondary circulatory engorgement, which prevents the absorption of the gas and renders peritoneal and other tissues less resistant to spreading infection.

3. The restoration of intestines to nonanatomical positions and the oversight, at operation, of kinking or prolapse.

4. Abrasions of the visceral peritoneum, followed by adhesions sufficient to cause angulation or to retain a displaced bowel in abnormal position.

To avoid intestinal irritation at operation it is important to have large or easily enlarged incisions to minimize the use of foreign substances, such as sponges and pads, within the abdominal cavity, relying instead upon posture of the patient, to manipulate the gut, when required, with a gloved hand, to avoid infection and exposure of intraabdominal parts to the drying effects of air or to all but body temperatures, failing which congestion follows (consequently as little evisceration as is feasible), to eliminate from the operating room all irritating solutions in bulk, such as plain water, bichloride of

mercury solution and alcohol, which upon the hands might gain entrance to the belly, and to exclude the use of all chemicals, such as phenol or iodine, employing instead the actual cautery, the effects of which are controllable.

Evisceration and faulty replacement of intestinal coils or displacement and angulation, following operative procedures, are frequent sources of unrecognizable mild intestinal obstruction. Concerning the position of small intestines Mall says, "the jejunum first arranged itself into two distinct groups of loops situated well up in the left hypochondriac region. Each group made more than a complete circle and both of them came in contact with the anterior abdominal wall. After this the intestine passes through the umbilical region to the right side of the body. Then the intestine recrosses the median line to make a few convolutions in the left iliac fossa after which it fills the pelvis and lower abdominal cavities between the psoas muscles." To a great extent misplaced intestines and purely mechanical disturbances will be restored after operation to normal position and overcome by physiological shifting of which the gut is capable. However, with any abdominal distention or in the presence of fresh adhesions this is made more difficult or impossible. Likewise an omentum placed in malposition or spread out and pulled down into the lower abdomen always tends to regain its natural position, carrying with it and kinking coils of intestine to which it may have adhered, or, becoming involved in the inflammatory process, it may press upon or constrict the intestinal lumen. Mechanical obstruction may have origin, moreover, in a mobile, prolapsed cecum, ileal kink (Lane), ptotic colon or voluminous sigmoid, all of which portions of gut should be inspected, when practicable, during operation.

Abrasions of the peritoneal surface of the gut is a most common and frequently unavoidable cause of postoperative intestinal stasis. The method of overcoming the effects of this traumatism by means of mineral oil introduced within the abdominal cavity at operation has proved effectual and safe, and the advantages of the procedure were fully demonstrated in the following case:

A patient, a woman 32 years of age, was operated upon early in January, 1913, for the relief of obstinate constipation and cecal distress, volvulus of the cecum was found and appendectomy and cecopexy performed. The patient left the hospital upon the seventh day and for a few days the bowel evacuations were natural but a certain amount of "gas" pain and attacks simulating increased peristalsis now occurred. The pain became severe at the pyloric region and was associated with vomiting which gave temporary relief. Upon each of the twelfth, thirteenth, and fourteenth days vomiting occurred three or four times and pain, coming at intervals, was controlled by lavage. Upon the fifteenth day vomiting became more frequent, occurring every two or three hours, colicky pains became severe and enemata resulted in the passage of a little gas and particles of feces. The temperature, which had been normal, rose to 100.5° at 4 P.M., the pulse remained under 90 but considerable general abdominal distention appeared. Two hours later, at secondary operation, coils of small intestines, beginning at a point about 1 foot from the ileocecal valve, lying to the left of the mesentery and filling the pelvis, were found matted together with extensive, fresh, soft adhesions, sufficiently firm to cause acute angulation in three places and constriction in others. Upon separating them, which was done by blunt dissection, areas of peritoneum were torn off and denuded portions of gut, aggregating approximately 10 square inches, remained. It was found necessary to break down adhesions at about twelve places, involving perhaps 8 feet of bowel. The site of absolute obstruction was near the cecum, the intestine distal was collapsed, that proximal greatly distended, but as usual it was the jejunum which suffered most in this respect. This part of the gut for 3 feet was distended to double its normal, black, but still presented a glistening peritoneal surface. The peritoneum ruptured in several places upon putting back the jejunum, evisceration having been required; its walls were so thinned out and tense that sutures would not hold, and attempts in this direction were soon abandoned. Six ounces of liquid petrolatum or mineral oil were sterilized, poured into the abdominal cavity, and sponged over the coils of intestine. Approximately 5 ounces of oil were left within the abdomen, the fluid welling up into the wound upon closing the belly wall. Convalescence was uneventful, except for the occurrence of an extensive urticaria and temperature of 102° upon the fifth day, the temperature remaining at other times under 101° F. The pulse rate after leaving the table was 128 but soon dropped to below 100, no vomiting followed the operation, nor did "gas" pains, other than low colonic ones, relieved at once by rectal irrigation, reappear, but as a precaution cathartics were given early and persisted with for three weeks. The patient again left the hospital before the completion of a full seven days and is now in good health.

The writer has carried out a series of animal experiments showing the harmlessness and value of neutral mineral oil, used intraabdominally. In most simple abdominal operations its use is not required since prophylactic care will limit postoperative distress, but in all others the oil is of the greatest value when employed upon abdominal pads during operation or sponged gently upon intestinal coils previous to closure of the incision, excluding only areas where adhesions are desired and having care that all plastic procedures and intestinal anastomoses are completed before oil is introduced. In cases presenting extensive adhesions or widespread peritonitis, large amounts of oil (up to 6 or 8 ounces) are required to prevent recurrence or formation of adhesions, to limit the absorption of toxins from the peritoneal cavity, to assist nature in combating infection, and as a prophylaxis against intestinal stagnation, obstruction, spasm, and final paresis. In the case of more than moderate severity, intestinal spasm and stasis, together with abdominal pain, are largely eliminated and convalescence is more comfortable and safe, while the individual in dire straits at the time of surgical intervention has, postoperatively, manifoldly better chances of recovery.

Conclusions, based upon the peritoneal reaction to chemical irritation and upon the results of using neutral oil intraabdominally to control infection and effects of traumatism, both mechanical and chemical, as observed in guinea pigs and dogs,* are as follows:

1. Iodine, mercuric chloride solution, carbolic

*Experimental studies carried out, through the courtesy of Dr. S. P. Beebe, at the Loomis Laboratory, Cornell University Medical School.

acid, alcohol, etc., applied to the peritoneum, rapidly spread beyond the area intended, through capillary action and affinity for the tissues, destroy the endothelial cells, cause an excessive exudate and tend to produce permanent adhesions.

2. Olive oil, containing fatty acids, and commercial liquid petrolatum, the impurities in which are acids, rosins, fats and oils, both animal and vegetable, combining irritating substances with a bland oil, produce inflammation of intact peritoneal surfaces, as is shown by the occurrence of a watery hemorrhagic exudate, which differs, however, from that which takes place in the absence of oil, in that agglutination and organization do not follow.

3. Bland, nonirritating oil, represented by a purified liquid petrolatum obtained from Russian oil, causes none of the changes occurring in the process of adhesion formation, which are endothelial cell injury, coagulable exudate, agglutination, organization, and finally connective tissue and fibrous scar formation. The oil has no appreciable chemical action upon the tissues nor deleterious effect upon the animal and is slowly absorbed.

4. Oil, used intraabdominally in sufficient quantity, prevents, to a great extent, the formation or recurrence of adhesions.

5. Oil fills the lymphatic channels leading from spaces denuded of peritoneum or opened by incision, thus limiting septic absorption, and, through preserving the endothelial cells, prevents extension of destructive processes.

6. Oil is used to advantage, intraabdominally, in place of salt solution, upon abdominal pads, and to protect and lubricate the abdominal contents, thereby eliminating or minimizing postoperative intestinal statsis, vomiting, and abdominal pain.

THE DETECTION OF DISTURBANCES OF THE DIGESTIVE TRACT BY THE EXAMINATION OF THE FECES.*

By CHARLES CLYDE SUTTER, M.D.,

ROCHESTER, N. Y.

The greatest stride made in medicine in the past 50 years is probably that which deals with the diseases of the digestive tract. Since Brinton's pathological and clinical investigations, which were summed up in his "Lectures on Diseases of the Stomach," our knowledge of gastrointestinal diseases has been revolutionized by the use of the stomach tube in diagnosis, the information gained through surgery, and recently by the use of the Röntgen rays in diagnosis. These measures have taught us the true significance of many of the symptoms which were, until quite recent times, universally misinterpreted. Although the significance of certain symptoms is now clear, their actual cause is in many instances as obscure as ever. With the help of our modern methods of research it should be possible to throw light upon some of the obscurities.

Probably the most neglected of all our modern methods of investigation is the examination of the feces. Discrepancies have occurred between clinical observation and laboratory findings, and this has led some to consider laboratory findings of little value in their relation to gastrointestinal disturbances. Many of these discrepancies have arisen from faulty technique, from forming conclusions from a single specimen, and from the lack of proper interpretation of the laboratory findings. Persistent and routine examinations are often necessary to detect true gastrointestinal conditions. No laboratory finding should be taken as conclusive without the aid of an examination of the gastric contents, the urine, the blood or the sputum; without the aid of a careful anamnesis and a careful and complete physical examination of the patient.

Gastrointestinal pathology more than any other department of medicine shows the influence of nonhygienic living, worry, and the strenuousness of modern daily life. It is therefore of the greatest importance to determine the difference between pathological and functional diseases of the digestive tract, since the accuracy of this knowledge determines the therapy. Organic diseases of the digestive tract require local treatment, while nervous or reflex disturbances are to be treated with reference to the primary cause. Indiscriminately, the term "intestinal indigestion" is often given to the various derangements, both organic and inorganic, and the treatment is carried out upon purely empirical lines. Quite frequently this is productive of good results, but, on the other hand, many conditions require careful and scientific diagnosis. Our knowledge of the physiology and pathology of the intestine is more scanty and more uncertain than that of the stomach because the intestine is practically inaccessible, and its contents reach us only after the chyme has been subjected to many complex digestive and absorptive processes.

Many efforts have been made to elaborate a method of clinical examination of the feces that would give reliable information in regard to functional disturbances of intestinal digestion. To Adolph Schmidt, of Halle, must be given the credit of devising a method which has put our knowledge upon a more scientific basis. By the use of the Schmidt diet, or the diet modified by Steele and others to conform to the American dietary, fairly reliable data can be obtained concerning the power of the intestine to digest certain foods like potato starch, butter fat and muscle fiber. If there is found an excess of muscle fiber, neutral fat or fatty acids, or potato cells, we assume that proteid, starch or fat digestion is imperfect. A correct interpretation of the exact variations from the normal is almost impossible because the digestive processes in the intestine are very complex, and are probably interactive to a certain extent. An excess of undigested meat fiber in the feces does not always indicate failure of the pancreatic secretion alone. Other factors must be given consideration, such as

*Read before the Hospital Medical Society, Rochester, N. Y., March 27, 1913.

the presence or absence of trypsin or its activating enzyme, enterokinase, gastric digestion, proper mastication, and the rapidity of passage of food through the digestive tract. On the other hand, there may be considerable disturbance of the pancreas, but if there is any trypsin present there may not be an excess of undigested meat fiber present in the feces.

The stools in pancreatic disease are usually exceedingly bulky, soft, greasy and pale. They contain undigested fat and muscle fiber and are extremely offensive. Musser is inclined to lay as much stress upon their macroscopic appearance as upon their microscopic and chemical examination. Patients frequently state that they suffer from diarrhea, but this is usually an error, for, although the stools are bulky and soft, they are not lqiuid in consistency. Marked increase in the daily average residue of feces, in the Schmidt diet, is considered by Musser to be suggestive of pancreatic disease.

Recent investigators have been advocating methods for the detection of neutral fats, fatty acids, and soaps. The stools usually show about 80 per cent. fat in the form of neutral fats, 10 per cent, as split fats, and 5 per cent. as soaps. Diminution of the split fats below 70 per cent. of the total fat points to pancreatic disease. Saathoof[1] uses a stain (90 c.c. glacial acetic acid, 10 c.c. 90 per cent. alcohol, and a knife point of Sudan III), in addition to the heat method of distinguishing between the neutral fats, fatty acids, and soaps. He discusses the importance of the findings in cases suggesting liver and pancreatic disease, in metabolic disturbances, and in bowel trouble in infants. He found an abnormally large proportion of fat in the stools of patients with exophthalmic goiter and other thyroid derangements, and the course of the cases could be followed by the increase or decrease of the fat in the stools. The normal amount of fat in the feces varies between such wide limits that it is quite difficult to determine whether there is actually an increase of fat in the stool. The most practical value in the examination of the stool for fat is in watching the digestion and absorption of the various amounts of fat. Pathological starch fermentation means poor starch digestion, and indicates, as a rule, alteration in the pancreatic secretion. An attempt is now being made to estimate the function of the pancreas by the dosage of anylase in the feces.

The amount of mucus in health is small and intimately mixed with the feces. It usually requires the use of the microscope or chemical tests for its recognition. Its macroscopic or microscopic appearance indicates, as a rule, the presence of inflammation of the mucous membrane or some deviation from the normal physiological condition. The form of mucus usually indicates in a general way the part of the intestine from which it comes. Mucus without feces or surrounding the feces shows the colon is inflamed. When mixed with the feces the upper colon or small intestine is inflamed. Mucus when bile stained indicates disease of the small intestine, and if colorless, catarrh of the large intestine or lower part of the small intestine is present. There are many exceptions to these rules. The important exceptions are: (1) Thin mucus spread over the surface of a hard dry ball of feces without evidences of a rectal inflammation; (2) hyper-secretion of mucus with discharge of the mucus in the form of casts, causing the so-called mucous colic.

In cases of colicky abdominal pain, where cholelithiasis is suspected, the feces should be examined for biliary concretions. "A normal fresh stool will give a pink color with mercuric chloride. A green color of part or all of a stool, by the sublimate test, is pathological, except in children. It means a too short period of passage through the intestine and that time for a normal reduction process of the bilirubin into hydrobilirubin was lacking. If a color reaction of any kind is absent it indicates a very fat stool, or an absence of bile in the intestine."[2] Colorless feces"[2] without jaundice does not always indicate defective supply of bile to the duodenum. It may also be present in intestinal catarrh, tuberculosis of the digestive tract, malignant disease of the intestine, septic abdominal disease, chlorosis, and leucemia. The diet of the patient must always be considered, as a milk diet will give a light colored stool, and has no significance.

The fermentation test should be made with Steele's modification of Strasburger's fermentation apparatus. "The fermentation test should show practically no gas, and the original reaction should be unchanged for twenty-four hours. If more than one-third of the tube is filled it is pathological. If, then, the reaction is decidedly more acid, it is a carbohydrate fermentation; if alkaline and with a foul smell it is a fermentation of albumins."[2]

In recent years considerable attention has been paid to the clinical importance of recognizing minute quantities of blood in the gastric contents and in the stools. The stools are examined in preference to the gastric contents because of the greater ease in securing material and because there is less likelihood of confusion by blood of no significance. Practically the presence of occult blood is of decided value in the detection of gastric and duodenal ulcer and of cancer of the gastrointestinal canal because it occurs with considerably more frequency and regularity in these two affections than in any other condition of the alimentary tract. Its absence is of equal or greater value in the diagnosis than its presence. Its presence is of value only when sources of bleeding that have no significance are excluded. The presence or absence must not necessarily be conclusive in establishing or confirming a diagnosis of ulcer or malignancy of the gastrointestinal tract, yet it should play a considerable part in the routine laboratory examination. When one considers the simplicity of this test and the valuable aid of this clinical test in establishing or confirming a correct and early diagnosis, it is surprising to learn how infrequently it is used. The presence or absence of occult blood is very important as a guide in the dietary of the patient and in watching the progress of the case of gastric or duodenal ulcer. Its presence is of great value in denoting recurrence after the removal of a cancer.

The best methods of examination for the detection of occult blood in the feces is probably the simple but very delicate benzidine test, to be followed in case a positive result is secured, by the Weber modification of the guaiac-turpentine test and the Klunge aloin-turpentine test or the Boas phenolphthalein test. A positive result should not be accepted unless the patient has first been placed on a meat free diet and the stool marked off by giving the patient a capsule of charcoal. The first black stool marks the first stool passed after the exclusion of the meats from the dietary of the patient. Red meats, carmine, swallowed blood,

hemoptysis, epistaxis, and menstruation will give a positive result, so they must be excluded. Cirrhosis of the liver, purpura of the gastrointestinal tract, tuberculous ulcer, typhoid ulcer, hemophilia, hemorrhoids, fissure and fistula of the rectum are rather easily ruled out. A positive result after the exclusion of the above points rather strongly to either ulcer or malignancy of the digestive tract. Pus and red blood corpuscles are rarely found in the stools unless they come from low down. If from the small intestine or high up in the colon, they are destroyed in the passage through the bowel.

The diagnosis of intestinal autointoxication is usually rather difficult, for the picture is not always clear and well defined. Aside from the well defined forms there are masked and insidious forms which require more demonstrative, more convincing proof. For these we must have recourse to a study of the blood, urine and feces. An examination of the feces gives some information but not absolute proof. The examination may give us the kind and degree of the digestive disturbance, whether nitrogenous, fatty or carbohydrate, but gives no assurance of the diagnosis. The anaerobic flora always corresponds to a considerable increase in intestinal putrefaction. In our examination we should determine if the intestinal flora is abnormal and if the proteolytic anaerobic bacilli predominate, for these findings give important therapeutic indications.

Intestinal parasites are more common in the United States than is generally supposed and a patient presenting vague abdominal symptoms, or the symptoms commonly grouped together under the name "chronic dyspepsia," not otherwise explained, should have his feces examined for the evidences of infection with intestinal parasites. The diagnosis of helminthiasis from the stools may be very easy or it may require considerable painstaking research. If segments of the tenia pass in the stools, the diagnosis is evident. In other cases, a diagnosis can only be made by finding the ova in the feces. If a differential blood count shows an eosinophilia the feces should be searched for intestinal parasites. In a case of chronic diarrhea, not otherwise explained, the feces should be searched for cercomonas infection.

Routine examination should be made of all cases of typhoid convalescents for the typhoid bacillus. Lentz has shown that about four per cent. of all cases of typhoid may be expected to become chronic carriers. Up to the present time the isolation of the typhoid bacillus from the urine and feces has been looked upon as difficult and uncertain, but with the Hesse, the Endo fuchsin or the Russell media it becomes more easy. Russell has found the Endo fuchsin agar medium routine simple and reliable. "With this medium typical colon colonies are colored with the fuchsin of the medium and are readily differentiated from typhoid. In some stools there are many 'slow colonies,' which in the first twenty-four hours are practically indistinguishable from typhoid, and as such colonies may give rise to considerable confusion the plates must be incubated for forty-eight hours or some special method used to bring out the colon characteristics. With Russell's double sugar medium typhoid, paratyphoid and dysentery bacilli give a characteristic appearance. This medium enables one to throw out of consideration almost all the colons and many other organisms which bear some resemblance to typhoid on the Endo plates, and which leaves the culture in a suitable condition for macroscopic agglutination on the second day following the receipt of the material."[3]

The microscopical examination of the feces for tubercle bacilli is of little value, for many bacteria make their appearance in the feces with the morphology and staining characteristics of the tubercle bacilli which, however, fail to prove themselves as such. Pappenheim's stain should be used, and if the diagnosis is important animal inoculation should be done.

Many of the laboratory methods are too slow and difficult to be of use in the routine examination of large numbers of patients and many require a specially trained physiological chemist to carry out the investigations. On the other hand, there are many simple tests that can be carried out by the general physician with much benefit. It has not been the aim of the writer to make any contribution to the literature on the examination of the feces, but rather to urge the more frequent employment of the various methods at our command as a diagnostic aid in the detection of many more or less obscure disturbances of the digestive tract.

EXPERIMENTS ON INTRADURAL ANASTOMOSIS OF NERVES FOR THE CURE OF PARALYSIS.*

By WILLIAMS B. CADWALADER, M.D.,

PHILADELPHIA.

INSTRUCTOR IN NEUROLOGY AND NEUROPATHOLOGY, UNIVERSITY OF PENNSYLVANIA, CLINICAL ASSISTANT TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES,

AND

J. E. SWEET, M.D.,

PHILADELPHIA.

ASSISTANT PROFESSOR OF SURGICAL RESEARCH, UNIVERSITY OF PENNSYLVANIA.

Anastomosis of peripheral nerves for the cure of paralysis has been successful in certain cases of facial paralysis, but when applied to nerves of the extremities the results have not been very encouraging. In 1908 Kilvington† conceived the idea of crossing the intraspinal motor roots of the spinal cord for the relief of paralysis of the bladder which results from injury of the lumbosacral spine. He performed this operation experimentally upon a series of dogs, and the results seemed so encouraging that he afterwards operated upon a man suffering with incontinence of urine caused by injury of the lumbosacral spine. Unfortunately Kilvington did not record any post-mortem examinations. Microscopical study of the nerves would have made his experiments much more valuable.

It is evident that if this operation could be proven to be practicable in man for the possible return of

*From the Laboratories of Neuropathology and Surgical Research, at the University of Pennsylvania.

†Kilvington: *British Medical Journal*, April 13, 1908.

at least partial function in an already paralyzed bladder, even though absolute cure could not be assured, then it might be a justifiable procedure in certain carefully selected cases. Moreover, it might be possible to obtain beneficial results in other forms of motor paralysis. As the experimental evidence indicating the usefulness of the procedure did not seem to be conclusive, we determined to attempt to anastomose the intradural motor roots of the spinal cord of normal dogs and to study the symptoms produced as well as the microscopic appearance of the nerves after death.

Without going into long details we will at once state that none of our dogs presented any clinical evidence of restored function. The loss of function produced by the operation itself was permanent, because regeneration of the nerve roots had not taken place. Each of our cases was a failure so far as the return of function was concerned, although the surgical technique appeared to be satisfactory and adequate. Microscopical examinations showed that considerable fibrous connective tissue had developed within the dura and about the nerve roots which had been sectioned and reunited. The proximal stumps of the cut roots always developed bulbous ends, similar to those observed in peripheral nerves after section. The distal segments were degenerated and did not show any evidences of new axis cylinders which might have grown and extended downward from the central segment, and in addition there was a considerable accumulation of fibrous connective tissue and leucocytic infiltration at the point of union which still separated the united ends of the nerves. We believe that it was this excess of scar tissue formation which was the most important factor in preventing complete regeneration of nerve tissue and subsequent return of function. In the absence of so much scar tissue regeneration might have been perfected. In dogs the intradural tissues are exceedingly delicate and a certain amount of traumatism cannot be avoided, even with perfect technique. But unless a minimum amount of connective tissue proliferation about the site of anastomosis be assured, the ultimate regeneration of nerves and return of function would appear to be impossible. However, it should not be forgotten that a certain amount of connective tissue proliferation takes place normally about the united ends of cut nerves. But whether an excess of connective tissue is entirely due to proliferation of the perineural tissues or to the endoneural tissues or to both, does not seem to be positively determined. We are inclined to believe that if the perineural proliferation could be greatly diminished, or better still, entirely obviated, then regeneration might take place and the operation might become practicable and exceedingly useful in carefully selected cases.

In order to determine this point we operated upon a dog in January, 1913. The median nerve of each side was sectioned; on the right the ends were joined without unusual precautions, and the wound closed; but on the left side both ends of the divided nerve were cautiously drawn into a very delicate celloidin tube about one and a half centimeters long, the ends of the nerve were carefully approximated inside the tube and then united and fixed in place with silk, and the wound repaired. After three months had elapsed, even though too soon for perfect restoration of function, the dog was killed and the nerves were examined microscopically. Both nerves proved to be undergoing regeneration, but it was not nearly completed and it was uncertain whether the nerve which had been enclosed in celloidin was in a more favorable condition than the other, still it was certain that an excess of scar tissue had not formed. We still have a series of animals under observation in which peripheral nerves were sectioned and drawn into celloidin tubes and united. This method was also applied in crossing and joining the intradural spinal roots, but as yet no conclusions would seem justified, as only three months have elapsed since the operations were completed.

No doubt intradural root anastomosis could be much more easily done in man than in dogs, for the tissues of man are so much firmer and the nerve roots larger and less easily damaged therefore the chances of excessive proliferation of fibrous tissue would be diminished. But we do wish to emphasize the extreme difficulty of determining whether or not improvement which might occur after operation should be attributed solely to the nerve anastomosis and not to some other cause. It is evident that proof would be exceedingly difficult to obtain; therefore it is all the more important that opinions should be cautiously expressed. Furthermore, it is well known that considerable function can be regained long after an injury to the spinal cord.

We have had under observation in the service of Dr. John K. Mitchell at the Orthopedic Hospital and Infirmary for Nervous Diseases two cases, both men, who had fallen from high scaffoldings and had received severe injuries of the lower lumbar spine which caused profound paraplegia and incontinence of urine. Both these patients have been carefully watched since the time of the injury; one occurred in 1907 and the other in 1910. For the first year after injury improvement in both cases was insignificant, yet during the second year partial recovery of motor power was very distinct; considerable power of the lower extremities was regained and the function of the bladder became nearly normal. One of these patients (Willetts) continued to improve, even during the third year after the accident. All the usual therapeutic measures had been carefully carried out, such as massage, electricity, etc., but operation had not been done.

Dog I.—Dark brindle male: Operation November 8, 1911. The seventh lumbar anterior root of the left side was cut intradurally close to its point of exit from the dura, and the first sacral anterior root of the same side was cut close to the spinal cord within the dura, and its peripheral end was joined by a single silk suture to the proximal end of the seventh lumbar root, and the peripheral end of the seventh root was joined to the proximal end of the first sacral root. The dura was closed, and wound repaired, and iodine collodion used for dressing. Recovery from operation was normal. The next day there was decided weakness of the left leg. Dog could run or walk fairly well, but there was a tendency for the toes of the left hind foot to be spread out more than normal, and the whole leg was abducted. The posterior thigh muscles were weak; the sphincters were normal. The knee jerk was decreased on the left. The left leg was not flexed with as much power as the right. December 5, 1911: Atrophy of the posterior thigh muscles and decided weakness of left leg. June, 1912. Condition much the same; atrophy was marked, paralysis had not improved. Post mortem, December 20, 1912: No change in condition previously noticed. There were many adhesions from the surrounding nerve tissues and the dura and nerves were adherent. Microscopical examination showed complete degeneration of the peripheral segments

of both the seventh lumbar and the first sacral roots. At the point of surgical union there were many leucocytic cells and much connective tissue. Axis cylinders growing from the proximal segments seemed to end in this connective tissue.

Dog II.—Black and tan female. Operation November 20, 1911. The sixth root was divided intradurally and the proximal end was joined to the peripheral end of the seventh root. Wound repaired as usual. The day after operation there was decided weakness of all the movements of the left leg, but paralysis was not complete. Some power of flexion of the thigh remained. January, 1912: There was decided atrophy of all the thigh muscles without any return of power. March, 1912: Atrophy was profound. No return of power. There was contracture of the posterior thigh muscles so that the leg was held in flexion. June, 1912: No change. General health good. Post mortem, November 19, 1912. As in the other cases the dura was adherent to the roots which had been sectioned and there were many adhesions surrounding the nerve roots so that they were identified with great difficulty. Microscopically the peripheral segments as before were severely degenerated as were the proximal segments. Many leucocytes and connective tissue cells had accumulated at the point of union—within the anterior horns of the left side in the sixth and seventh lumbar segments many of the ganglion cells were swollen and pale as compared with those of the opposite side, some seemed to have entirely disappeared.

Dog III.—Short haired black and tan dog, bobtail. Operation November 27, 1911. The sixth and seventh motor roots on the left side were cut, and their ends were approximated as carefully as possible with a single silk suture. The wound was repaired as before. Next day there was incomplete paralysis of all movements of the left leg. January, 1912: Decided atrophy of all the thigh muscles. March, 1912: No return of power; otherwise the same. Post mortem, March 28, 1912. Microscopical examination: Degeneration was complete in all the intradural portion of the sixth and seventh lumbar roots. The cut ends were joined by fibrous tissue, but there was no evidence of regeneration of nerve fibers. The roots were closely matted together and firmly bound to the dura by many adhesions. Identification was very difficult.

Dog IV.—Black and white rough coated male dog. Operation November 28, 1911. The sixth and seventh lumbar roots on the left side were cut, and their ends carefully approximated without suture. The next day there was incomplete motor paralysis of the left hind leg. January, 1912: Decided atrophy of all thigh muscles. February 14, 1912: No change, only no return of power. Post mortem, February 28, 1912. There were many intradural adhesions binding the cord, and the cord was firmly attached to the dura. Also adhesions were found about the sixth and seventh anterior spinal roots. It was very difficult to distinguish one from another. Microscopical examination showed that regeneration had not taken place though here and there new axis cylinders appeared to be growing.

1710 Locust Street.

A NEW METHOD FOR THE DETERMINATION OF URIC ACID IN MINIMUM QUANTITIES OF BLOOD SERUM AND OTHER FLUIDS OF THE BODY.

By P. ROETHLISBERGER, M.D.,

PRIVAT-DOCENT, UNIVERSITY OF GENEVA, SWITZERLAND.

This new method for determining uric acid in body fluids was first described in two articles which appeared in the *Münchener medizinische Wochenschrift* in 1910 (Nos. 7 and 45). The working out of the method since its completion is, however, somewhat different from the first description.

As stated in the above-mentioned articles, the value of the method can be demonstrated by direct and by indirect proof. There can be no doubt that it is capable of determining uric acid; the results obtained with it are in agreement with those obtained by means of the analytic methods on large quantities of blood. Moreover, in cases where the analytic methods fail to show any uric acid, as in the blood of mammals, the new test is able to determine slight traces, while in the blood of gouty individuals and in bird's blood more or less considerable quantities of uric acid can be determined by this method.

The exactness of the method has been increased considerably since its first description. With an exceedingly small quantity of blood, from ten to fifteen drops, five to nine analyses can be made simultaneously; there is no loss of time in making this number. In this way practically all risk of error is eliminated and the experimenter is able to arrive at a very exact average result.

Another advantage of the method is this, that it permits of frequent blood tests being made in short intervals of time, without inconveniencing the patient; up to the present, such repeated examinations have not been possible. I venture to say that these numerous tests should do much to clear up dark points in the pathology of gout and other diseases, and to determine the importance of uric acid in all cases.

The fact that quantitative blood tests for the determination of uric acid have been made infrequently in the past is not astonishing when one considers the great amount of blood required for such tests, and the difficulty and delicacy of analytical analyses. Unfortunately, Garrod's method, though simple, is not reliable, and it also requires from ten to twenty cubic centimeters of blood. Kowarski's new method (*Deutsche medizinische Wochenschrift*, 1911, No. 24) demands only ten cubic centimeters, but takes up much time, and is complicated. Considering these drawbacks, the new method meets a real need, and should prove indispensable to those of the profession especially interested in this branch of medicine. It is quite as simple as the hemoglobin test; the operator draws the blood from the finger tip or the lobe of the ear. The method possesses great advantages over the older procedures in that it requires no special training or chemical equipment. Finally, an important factor to be taken into consideration is the relatively small amount of time necessary to accomplish the test; it requires only minutes, not hours of time to obtain exact results.

The technique of the method is as follows: A small quantity of blood is drawn from the finger tip or the lobe of the ear into a special glass tube, from ten to fifteen drops being usually sufficient for from six to nine tests, which are made simultaneously and serve to control one another. The glass tube must be kept in an upright position for several hours, until complete separation of the serum has taken place. If necessary—especially if placed in an even temperature—the blood may be kept from twelve to twenty-four hours. As can readily be seen, if kept for a longer period of time there will be loss of uric acid by fermentation or putrefaction.

The best environment for the test is a dark room with a red light, though equally good results may be obtained in a room with a subdued light, or one lighted by a small electric bulb placed at a distance of two or three yards. Two, three, or more strips of the reagent paper—a special kind of filtering paper impregnated with nitrate of silver—are placed on a glass slide. The silver paper should not be exposed to the light except during the time necessary for manipulations; in the intervals it must be screened. With a dropper, a fifteen per cent. solution of carbonate of soda is dropped onto the pa-

per, allowing a certain margin to surround each drop. The drops must be very small and must absorb quickly, leaving a perceptible round spot. After waiting two or three minutes, a quantity of the blood serum is withdrawn by a dropper from the glass tube containing the blood; it is dropped slowly onto the round spots made by the carbonate on the test papers. In two or three minutes more the strips of paper are lifted from the glass slide and placed to soak in a porcelain or earthenware dish filled with water. The nitrate of silver now dissolves, while the carbonate remains insoluble. The basin must be kept covered to protect the strips of paper from the light until the nitrate is totally dissolved, which generally requires at least thirty minutes. They may be left to soak much longer without harm. The strips are now ready for fixation. They should be removed from the basin and placed in a solution of ammonia (one part of pure ammonia to four parts of water), which removes any unreduced carbonate of silver. Five minutes are sufficient for this process. The strips of paper are then placed in clean water screened from the light, to wash them thoroughly and to remove the ammonia and remains of the salts of silver. After remaining for several hours in the water, the strips are dried between blotting or writing paper, care being taken to protect them from the light. The dried strips are then ready to be placed under the scale; a color scale is necessary for the determination. By comparing the color and the intensity, the degrees of reaction and the proportion of uric acid contained in the blood can be determined. Only spots with distinct outlines are to be considered.

An immense amount of time has been spent in analyzing the uric acid content of the urine, and the results obtained have given but meager conclusions as to the quantity contained in the blood, the quantity not eliminated by the kidney being unknown. It must be kept in mind that the composition of the urine in all its substances is very variable, while the blood in a healthy organism is relatively constant. For these reasons, I believe that the described clinical method for determining the uric acid content of the blood must needs be of importance to the medical profession, particularly on account of the great simplicity of the analysis and the saving of time that is effected.*

AMBULATION AND FULL DIET AS FACTORS IN THE DIAGNOSIS OF GASTRODUODENAL ULCER.

By FRANK BETHEL CROSS, M.D.,
BROOKLYN, NEW YORK.
ATTENDING PHYSICIAN, METHODIST EPISCOPAL HOSPITAL.

The diagnosis of gastric and duodenal ulcer is frequently a matter of such difficulty and the physician so often misled in his recommendations of treatment, that this clinical note is offered for the purpose of calling attention to a much neglected feature in the conduct of suspected ulcer cases. I have reference especially to those subacute and chronic cases which seek hospital and sanatorium aid. In private office practice and dispensary service the situation does not usually develop.

It is a common experience with those in hospital service to find upon making rounds that such a patient, after his admission, has been put to bed on a light lacto-farinaceous diet. If this be continued, it will frequently be observed that the pain and vomiting cease, promptly or gradually in different cases, the patient begins to feel better, digestion improves under the influence of diet, physical rest and changed environment; the test-meals are found to be of themselves inconclusive and, in response to the reiterated demands of the patient, he is allowed up, permitted a moderately increased diet, and in a short time is discharged as an improved case of gastric neurosis, chronic gastritis, or some equally indefinite condition. The subsequent developments are typical; in order they are, return to work and the previous hearty diet, reappearance of the pain and distress after meals, and eventually the readmission of our patient to the hospital for further treatment.

All this can be in large measure avoided and neither patient nor physician misled, if the patient be *kept up and about and on his previous general diet while under study*. In this way the clinical picture retains its high lights, clearly and distinctly. Such pain and discomfort as the patient experienced when first observed, he continues to exhibit, and it is, I take it, the persistent and typical recurrence of the pain of ulcer which gives it its diagnostic value rather than any other characteristic it may possess. Under these circumstances, with the patient ambulant and on liberal diet, a diagnosis is reached while all symptoms are fresh and clear in his mind.

If the above plan be followed systematically in the routine conduct of such cases, fewer cases of ulcer will escape recognition, and this means much, as upon correct diagnosis rests proper treatment. Sufficient emphasis has not been laid upon these factors in diagnosis in the recent American literature of ulcer.

832 President Street.

*M. Schaerer, Sanitätsgeschäft, Berne, Switzerland, supplies a case containing all requisites for the new method.

Medicolegal Notes.

Expert Witnesses—Credibility.—In an action for personal injuries, where the testimony as to these consisted largely of that of expert witnesses on both sides, the gravest injury complained of was a fracture of the pelvis. Commenting upon the credibility of paid witnesses the court said: "There is no good reason why an expert whose relations to a case are purely professional, and whose competency exists perforce of his profession, should not be compensated, or why the fact of such compensation should of itself discredit him. So long as the present procedure as to expert witnesses is in force, the criticism upon it should not be directed to the individuals who by it alone must be brought to the witness stand."—Jacoby v. Brooklyn, Q. C. & S. R. Co., N. Y. Appellate Div., 138 N. Y. Supp. 486.

Compensation—Professional Courtesy.—In an action by one physician against another for professional services rendered it appeared that the plaintiff and defendant were both members of the staff of a hospital. While the defendant was performing an operation upon a patient, he desired the plaintiff's aid, and sent a telephone message requesting the plaintiff to come to the hospital to help him out. The plaintiff immediately came to the hospital and went into the private operating room. A woman was on the operating table. Her abdomen was open, and she was suffering from a hemorrhage. The defendant said to him: "Doctor, I wish you would finish this operation for me. This woman is bleeding. I can't control it." The plaintiff then finished the operation. The defendant was performing the operation for a fee of $10, and the patient was not strictly a charity patient, although the defendant was paying for the private room. It was held that the plaintiff was deemed to have rendered his services from the high sense of the professional obligation and courtesy which exists in the medical profession, and could not recover upon an implied promise by the defendant to pay for such service. The fact that the operation was not performed in the charity ward, and that the defendant received a nominal fee for his own services did not change the rule.—Gilday v. Hennen, N. Y. App. Div., 139 N. Y. Supp. 934.

New York, November 1, 1913.

THE THREE SUPRARENAL SYNDROMES.

THE history of the knowledge of the clinical importance of the suprarenal capsules dates back to Addison's description in 1855 of the disease that bears his name. Since then a large number of facts have been discovered showing that there are other conditions, besides the above, associated with disease or functional impairment of the suprarenal capsules. Langlois discovered the power which these organs possess in destroying muscle poisons; Dieulafoy perceived a relationship between asthenia and some pathological condition of the suprarenal capsules; Oliver and Schäfer revealed the vasoconstrictor function of these organs; Vaquez pointed out their rôles in the production of arterial hypertension; and Josué showed how these organs may even be responsible for atheromatous changes in the blood vessels. Still later, Sergent and Bernard delineated a clinical picture which they termed suprarenal insufficiency, and Bernard, Bigart, and Labbé were able to discern the anatomical basis of this condition as well as that characteristic of excessive suprarenal function.

Léon Bernard in *La Presse Médicale*, October 4, 1913, presents an interesting description of the three conditions which are now to be recognized as clinical entities, namely, the suprarenal syndromes. A lucid conception of the latter demands a knowledge of the histopathology of the suprarenal capsules, a knowledge to which Bernard and others have recently made ample contributions. In the first place, attention is directed to the cortical cells whose most important secretions are a series of lipoids including lecithin and cholesterin. The cortical cells which are also called "spongiocytes" have the function of neutralizing muscle poisons, and are therefore endowed with the myotonic function of the suprarenals. The medullary or chromaffin cells of these organs have been thoroughly studied. They contain the granules which produce the specific internal secretion of the suprarenals, so potent in raising arterial pressure—a capacity well described by the term angiotonic function. The third important anatomical element of the suprarenal capsules comprises the nerve cells which are in intimate relationship with the sympathetic system on the one hand and the chromaffin cells on the other.

The three suprarenal syndromes are named by Bernard as follows: the syndrome of *hyperépinéphric*, the syndrome of *hypoépinéphric*, and the syndrome *mélanodermique*. The first of these was studied by Bernard and Bigart in experimental intoxications in animals and was found to be associated with a swelling and fatty infiltration of the cortical cells and with a swelling of the medullary cells which are also surcharged with an excess of granules. The pathological picture of *hypoépinéphric* is just the opposite: the spongiocytes tend to disappear; the labile fat likewise vanishes; and the remaining cellular elements are small with finely granular protoplasm. Similar degenerative changes are present in the medullary substance whose cells are void of the adrenalinogenic granulations.

The syndrome of *hyperépinéphric* consists of clinical phenomena that depend upon an excess in the production of the specific secretion of the medullary cells. These manifestations are arterial hypertension, aortic atheroma, and glycosuria. The hypertension is at first transient. Later it recurs from time to time. Finally it becomes permanent, with its numerous well-known symptoms of vertigo, headache, etc., and its outcome in aphasia or transitory hemiplegia, convulsive crises, cerebral hemorrhage, acute edema of the lung, or sudden death. The presence of hyperglycemia in association with the evidences of arterial hypertension points particularly to a common origin in the excess of function of the suprarenals.

The syndrome of *hypoépinéphric* is characterized by the presence of muscular asthenia and diminished arterial tension. The former, which is the chief manifestation, may be so intense as to simulate a veritable paralysis. The arterial hypotension may express itself in a number of ways: there may be tachycardia, arrhythmia, a tendency to collapse and syncope, and peripheral vasomotor disturbances. There is also an impairment of the digestive functions. The nervous manifestations include midriasis, headache, delirium, convulsive or apoplectiform states, coma, and sudden death. Sergent has distinguished three different types of suprarenal insufficiency: the chronic, the subacute, and the acute. The last of these, which has not been recognized until recently, may be revealed under the guise of an acute poisoning, a peritonitis, or a meningitis. Many of the manifestations of acute infections or toxic conditions are to be attributed to suprarenal insufficiency. These manifestations are apt to occur particularly in diphtheria, scarlet fever, typhoid fever, erysipelas, and chloroform poisoning.

The syndrome *mélanodermique* is the one that has been recognized the longest time, but is the one that is least directly connected with the functional impairment of the suprarenals. It seems that these organs influence the cutaneous pigmentation through the intermediation of the sympathetic nervous system. The above syndrome may occur in lesions of the solar plexus. It is associated with disturbances in the suprarenal secretions, and may occur with slight or even minimal lesions of this organ. The melanodermic syndrome comprises the cutaneous and mucous pigmentation described by

Addison, and epigastric and lumbar pains. The syndrome may be perceived clinically in its pure state, provided that the pathological lesion undergoes a slow evolution and does not encroach too much upon the suprarenal tissue. If, however, the glandular portion is greatly invaded there are then superadded the symptoms of *hypoépinéphrie*, and the clinical picture of Addison's disease is then complete. Tuberculosis of the suprarenal capsules is the most common cause of the latter, but it may instead cause other manifestations, as the acute form of suprarenal insufficiency.

THE SOCIAL FACTOR IN THE DIAGNOSIS OF FEEBLEMINDEDNESS.

Even with the great advance made along technical lines in the diagnosis of feeblemindedness, the results have been far from uniform; and already those engaged in this work exhibit a wide latitude in the evaluation of these technical methods, and their results—specifically, in the value of the measuring scales of intelligence and their modifications. This fact was noted by Friedman (Medical Record, Nov. 2, 1912). More recently Glueck (*New York Medical Journal*, Oct. 18, 1913) illustrates the same point in an article dealing with work done in sifting the feebleminded from the stream of immigrants. Here, it seems that attempts at obtaining some show of uniformity in the examination even of immigrants of similar racial and environmental constitution through the use of the measuring scale principle have given such discordant results that it becomes a question whether it will not be necessary to disregard the scale principle entirely, or to commence the construction of a more elastic method of measuring intelligence. Yet these results, while discouraging, to be sure, are nevertheless helpful, because they act as checks to an only too natural but unhealthy tendency on the part of workers in such an especially difficult field as this, to be carried away by the enthusiasm of first success, and to overlook factors that would promise a larger though not so quickly attained measure of success.

The difficulty with the measuring scale principle is that of determining the normal standard with which to compare the defective. Jordan's definition of the normal—that individual who can take care of himself and have something left over for the common welfare—while rather broad and without limitation has not been improved upon, and thus far sums up our entire knowledge of the normal. This definition embraces also a modern and to be sure the material conception of success. In other words, it bears out the oft-repeated epigram that a man is not what he is but what he has. The immigrant, cited by Glueck, whose actual age was 35 but whose mental age was only 10, who nevertheless not only provided for his family but had money and property besides, might well be included in the modern class of the successful rather than among the feebleminded. At any rate it is hardly consistent to set the yardstick principle of measurement to any individual without at least having it corrected to conform to this material normal.

The test for the detection of the feebleminded is, then, somewhat social, a little material, but not entirely intellectual. But what is the social standard? It is as intangible as the intellectual standard. Every large social organization is composed of divers component organizations which go to make up the composite; and in this composite the lower social organizations are as necessary as the higher—the worker as well as the thinker. And is not the question of the normal and of the feebleminded one of evolution and one of atavism, in a social as well as in an intellectual sense, since social refinement goes only with an intellectual refinement? The higher social standards are evolutions from the lower; and may not the present social and intellectual atavists be equal to the normal of remote times? To the class of social and, therefore, intellectual atavism belongs the immigrant as a unit. In his own social organization he is normal; in our own he is backward or even feebleminded, but really atavistic. This suggests a question as to the constitution of the feebleminded in this lower order. This can be determined approximately at best, with a measuring scale principle, only by the formulation and by the use of a modification for each race, the average normal standard being drawn from the race to be tested. In this, the difficulty lies in becoming sufficiently acquainted with every race to construct such a standard scale. The immigration station offers the best opportunity for this work, for nowhere in the world of medicine do such opportunities for study and observation exist.

The measuring scale must be social in its limitations, and not universal in its application. Either the lower orders must be considered defective as a whole, or else normal as a whole, but each judged according to its own standard for normal. If the whole social fabric of the immigrant is lower than our own then the pertinent question arises whether, not being an inherent characteristic, it can be raised by environment, or, if inherent, does it account for the increase in the census of the feebleminded; and will admixture with them be likely to lower our own social fabric absolutely, or only in the Mendelian proportion of three desirable offspring to one undesirable for every crossing, which will, therefore, in the latter instance, have a tendency to be soon entirely eliminated.

Some Vagaries of Sex Teaching.

There appears to be no subsidence in the world-wide epidemic of teaching the young all about their sexual selves. Newspaper reporters, magazine writers, public school teachers, prelates, lecturers, social workers, novelists, and so-called leaders in the "feminist" movement, are tearing the last veil of secrecy and of modesty from a subject which our forefathers approached with the greatest caution and reserve. If the knowledge of sex were confined to the essential facts of sex and to the dangers of illicit indulgence, one might have no reasonable ground for objecting to this teaching. But this knowledge is peculiarly the kind that creates a keen appetite for more. One of the results of the modern campaign of moral prophylaxis is the wonderfully extensive knowledge of sex and

of its disorders which many young men and young women of the present day have acquired. Books on these subjects are readily accessible in many of the public libraries. Some of the classic authors of young ladies are Havelock Ellis and Albert Moll, not to mention the host of writers in the magazines whose candor equals their indiscretion in arousing a prurient curiosity in many young readers. But this is not all. The small child must get a share of this important knowledge. In the latest of the Edward Bok Books of Self-Knowledge for Young People and Parents, entitled "The Changing Girl," by Caroline Wormeley Latimer, a book that is written for the *girl of ten to fifteen*, we find the following: "From time immemorial girls have been taught to suppress and conceal every vestige of emotion connected with sex, not only from the world at large but from themselves, and the result of all these years of repression has been to create a state of things in which sex instinct in women shows itself in indirect ways." Here is an epitome of Freud's psychology presented for the little miss of ten or twelve years to ponder over!

Half-Joint Transplantations.

On the subject of transplantation of vital and other organs necessary for normal existence, the public, and to a large extent the profession, are very poorly informed. A successful transplantation naturally leads to the belief that the procedure quickly comes into common use. Lexer's case of transplantation of the knee joint of a girl, with descriptions of her subsequent dancing on the partly heterogeneous member was considerably pieced out by the imagination. And remarkable as was the case, it is one which may not soon be duplicated for purely outside reasons, such as lack of proper grafting material, lack of patient's consent, or disinclination of the surgeon to take the risk. It is, therefore, of great interest to note that last summer, in Jena, Lexer himself published a comparatively modest case of half-joint transplantation at the wrist (*Münchener medizinische Wochenschrift*, September 30). The patient, aged thirty-three, had once submitted to extirpation of a tumor of the epiphyseal region of the right ulna. Several years later he broke his radius during a fall, and the *x*-ray showed that the break was due to a tumor of this bone. The lower end of the latter was resected and the stump of the ulna taken off with it. The tumor was sarcomatous. As a leg was amputated about this time, the lower end of the tibia was used to make good the defect of the radius, the malleolar process having been removed. A good functional recovery was obtained, and the new wrist was so good that it probably will not be necessary to replace the missing portion of the ulna.

News of the Week.

Non-Practising Professors at Johns Hopkins.—The General Education Board, which was founded by John D. Rockefeller, announced on October 24 an appropriation of $1,400,000 for the Johns Hopkins Medical School, Baltimore, the appropriation being granted for the purpose of reorganizing the Departments of Medicine, Surgery, and Pediatrics in the school. Through this reorganization, the professors and instructors in these departments will be enabled to withdraw from paid practice and devote their time entirely to teaching, hospital work, and research. At the request of the Board the fund thus given will be known as the William H. Welch Endowment for Clinical Education and Research. This is the first appropriation made by the General Education Board to a medical college. In explanation of it, the Rev. F. T. Gates, chairman of the board, said that the Trustees of the Johns Hopkins University and the Johns Hopkins Hospital and the Medical Faculty of the Johns Hopkins University had united in requesting of the General Education Board funds that would enable them to reorganize the departments of medicine, surgery, and pediatrics so that the professors and their associates in the clinic and the laboratories should be able to devote their entire time to their work. In making the gift the General Education Board has placed absolutely no restriction upon the freedom of these men. They will be in position to do any service that either science or humanity demands, and they will be free to see and treat any one, whether inside or outside the hospital, but they will accept no personal fee for any such service.

Rumored Endowment of Cornell Medical School.—The report that Col. O. H. Payne of New York had completed his benefactions to the Cornell University Medical School in this city by a gift of $4,000,000 for endowment, has been denied by the President of the University.

Radium for Philanthropy.—It is announced that the product of the newly discovered radium ore mines in Colorado is not to be placed on sale but is to be given first to the General Memorial Hospital, New York, for the treatment of cancer and other ailments, and as additional supplies become available, to the Johns Hopkins Hospital, Baltimore, and other institutions for the same purpose. The United States Bureau of Mines, it is said, will provide experts to supervise the mining of the ore and the extraction of the radium, a new method having been evolved which will reduce the cost of the process materially.

The Friedmann Serum.—At the International Anti-Tuberculosis Congress, which closed its sessions in Berlin on October 25, Dr. F. F. Friedmann declared that his serum would henceforth be available to medical men for use without restrictions. Cases of surgical tuberculosis showed by Dr. Friedmann at a clinic on the same day received favorable comment from Schleich and others of the Friedmann supporters.

Modern "Blackmailer."—An original method for extorting money was tried in Chicago recently. Several wealthy women of the city received letters, in which were daubs of some sticky substance, the writer of which declared that the receiver had become infected with deadly germs by the mere act of opening and reading, and that relief could be had only through a curative serum which would be supplied for the sum of $2,500 placed in a certain place in Lincoln Park. None of the women so approached yielded to the demands of this original blackmailer, nor have any of them suffered from the deadly bacilli said to have been contained in the letters. In fact, the sticky substance so described when examined proved to contain only a few moulds and harmless bacteria.

Plague in Russia.—An outbreak of plague is reported from Novopatrovsk, a suburb of the capital of the territory of the Don Cossacks, in Russia, and the place is under military quarantine. Eleven deaths had occurred up to October 19.

Posture League. — The American Posture League, having for its object the improvement of human health and efficiency through the medium of correct physical postures, was incorporated at Albany, N. Y., on October 22.

Personals.—Medical Director Lucien G. Heneberger of the United States Navy was placed on the retired list on October 17, after thirty years of service. Dr. Heneberger was surgeon on the battleship *Maine* at the time of her destruction in Havana Harbor.

Col. William C. Gorgas, chief sanitary officer of the Canal Zone, reached New York on October 20, and will shortly leave for South Africa, where he will undertake to check the ravages of pneumonia among the negro miners of that section. Col. Gorgas will be assisted in his work on the Rand by Dr. Samuel Darling, one of his colleagues at the Ancon Hospital, and Major Robert Noble, executive officer of the sanitary department of the Isthmian Canal Commission.

Dr. Christian R. Holmes, professor of otology in the Medical College of the University of Cincinnati, Ohio, has recently been elected dean of that institution, and has accepted the election, although, because of the pressure of other work, with some reluctance. Dr. Holmes' connection with the new City Hospital of Cincinnati, his prestige in the Academy of Medicine, and his influence throughout the city, all promise to make the University of Cincinnati one of the leading medical centers, and the medical school is to be congratulated on securing the benefits of his wide experiences and sane leadership.

Dr. Thomas Darlington, formerly Health Commissioner of this city, is the Tammany candidate for President of the Borough of Manhattan in the present municipal campaign.

American Hospital Ward.—The project of endowing an American ward in one of the hospitals of London, which was proposed some years ago, is now likely to be carried to completion, arrangements having been made with the London Hospital whereby one ward will be reserved for American patients, provided sufficient funds for its maintenance are forthcoming.

Memorial to Dr. Newcomb.—A memorial window to the late Dr. James Edward Newcomb of New York has been placed in the Hall of the Stony Wold Sanatorium, Lake Kushaqua, N. Y., a charity in which Dr. Newcomb was greatly interested, and dedicatory exercises were held there on October 26.

Smallpox in Connecticut.—Twenty cases of smallpox in the small town of Brooklyn, Conn., were reported on October 21, and it is feared that a large number of cases have been concealed among the mill hands of that section.

Church Eugenics Class.—The Mount Morris Baptist Church of Harlem, New York, is the first in this city to start regular classes for the teaching of eugenics to both men and women. The officials believe that if the church is to assume authority over the marriage contract its duty is to educate its young people in the significance of the propagation of the race.

Politics in Hospital Service.—The Civil Service Reform Association of New York has protested to the Governor of the State against what it describes as "political appointments in the State Hospital service" during last July and August. The protests have to do particularly with the appointment of the present secretary to the State Hospital Commission, the creation of the position of "confidential accountant," and the appointment of a secretary to the purchasing committee, the latter two being exempt from the civil service.

French Vital Statistics.—A review of the vital statistics of the French nation for the last six months of 1913 shows an increase in the birth rate, the number of births during that period being 387,512 as compared with 378,807 in the corresponding period of 1912. This increase, however, is more than counterbalanced by an increase in the number of deaths, which numbered 376,508 or 11,875 more than the total for the first six months of last year, so that while the excess of births over deaths for the first half of 1912 amounted to 14,712, for this year the total was only 11,004.

City Death Rate.—The death rate for New York City for the week ending October 18 was the lowest ever recorded in the history of Department of Health, being only 11.20 per thousand of population. The total number of deaths for the week was 1,153 as compared with 1,243 for the corresponding week of last year. There was a big drop in the infant mortality, and decreases occurred also in the number of deaths due to scarlet fever, whooping cough, typhoid fever, and lobar and bronchial pneumonia.

The New York Laryngological Society, which was founded in 1873, will celebrate the fortieth anniversary of its organization during the latter part of the present month. The event is especially interesting, from the fact that this was the first society of its kind to be established, the earliest to imitate its example, either in Great Britain or in Europe following it by more than ten years. Twenty-five years ago the Society was merged into the Academy of Medicine, becoming the Section of Laryngology and Rhinology. A formal meeting at the Academy of Medicine has been arranged at which addresses will be offered and a bronze tablet and other memorials commemorating the occasion will be presented.

Meeting of Pediatric Societies.—On the invitation of the New England Pediatric Society, a joint meeting of that Society with the Philadelphia Pediatric Society, the New Jersey Pediatric Society, and the Pediatric Sections of the Medical Society of the State of New York and of the New York Academy of Medicine will be held in Boston on November 8. During the day clinics will be held at several hospitals. There will be a dinner at the University Club at 6:30 P.M., and at 8:15 P.M. the combined societies will meet in John Ware Hall, Boston Medical Library, to listen to papers on the "Bacteriological Diagnosis and Treatment of Alimentary Disease in the Infant and Child," by Dr. Ralph Vincent of London; "Investigations in Vulvovaginitis, by Means of the Female Urethroscope," by Dr. John F. Sinclair of Philadelphia; " Active Immunization in Diphtheria by Toxin-Antitoxin Mixture," by Dr. William H. Park of New York, and "The Position of the Stomach in Children," by Dr. James Warren Sever of Boston. Dr. James S. Stone will preside.

Harvey Society Lecture.—Dr. Charles V. Chapin of the Health Department of Providence, R. I., will lecture before the Harvey Society at the New York Academy of Medicine, on Saturday evening, November 1. Dr. Chapin's subject will be: "The Air as a Vehicle of Infection."

Red Cross Seals.—The State Charities Aid

Association, which has charge of the sale of the Red Cross Christmas seals in New York State outside of New York City, is preparing 10,000,000 seals between December 1 and the New Year. This will mean $100,000 to be used in the campaign against tuberculosis. Last year $60,000 was raised in this way.

Cancer Hospital.—The new Hospital of the New York State Institute for the Study of Malignant Disease at 113 High Street, Buffalo, N. Y., will be opened today, November 1, with appropriate exercises.

Operative Clinic.—The New York Hospital announces that an operative clinic will be held at the hospital on Saturday mornings from nine to twelve throughout the year, by Dr. C. L. Gibson, attending surgeon, and Dr. J. M. Hitzrot and Dr. J. B. Lee, associate surgeons, on the first (Cornell Medical College) surgical division.

Barnier Solarium.—The Methodist Episcopal Hospital of Brooklyn, N. Y., on October 20, opened the new solarium erected for the hospital by Mrs. E. Barnier Shaw, in memory of her parents, John J. and Elizabeth B. Barnier.

Whooping Cough Camp.—The Trustees of St. John's Guild, New York, recently decided to use their floating hospital, the *Helen C. Juillard*, during the winter season as a whooping cough camp. The camp will be operated in connection with the Department of Health. The Trustees have also extended the work of the Seaside Hospital at New Dorp by ordering that it be kept open during the winter as a convalescent hospital.

The Von Ruck Serum Tests.—Some disagreement is said to have occurred between the officials of the Public Health Service and Dr. Von Ruck of Asheville, concerning the details of the testing of the latter's anti-tuberculosis serum, and it is probable that the tests will be transferred from Asheville to Washington, and continued in the laboratory of the Public Health Service. Surgeon John Anderson was directed on October 19 to proceed to Asheville for a conference regarding the investigation of the remedy.

Dr. Just Lucas Championnière of Paris, honorary surgeon at the Hotel-Dieu, a member of the French Academy of Medicine, ex-president of the French Surgical Society, and a commander of the Legion of Honor, died suddenly on October 22, while delivering an address before the Academy of Sciences. Death was due to an attack of angina pectoris.

Dr. Bulkley's Lectures.—Through an error the date of the opening of this course of lectures on diseases of the skin was given in a recent issue as November 15. The first lecture will be given on Wednesday, November 5, at 4:15 o'clock.

Fire Near Hospital.—A fire on the second floor of the disinfecting station of the Department of Health at Sixteenth Street and the East River, New York, caused some alarm among patients in the Willard Parker Hospital and the Hospital for Scarlet Fever and Diphtheria Patients nearby. The flames were subdued, however, without serious results.

The Physician's Part.—In an address before the Medical Club of Philadelphia on October 17, Dr. John Grier Hibben, president of Princeton University, in discussing the menace of social diseases, said: "What is needed above everything is that zeal should be balanced by sanity and guarded by expert knowledge. As regards the menace of the whole catalogue of social evils the physician is preeminently the man who knows. His counsel and his warning will be sober, sane, and steady. We look to you for the word of wisdom and the spirit of sacrifice which will enable us to solve the great human problems of the day."

Maternity Hospital Opposed.—The application for a certificate of incorporation for the Bronx Maternity Hospital, New York City, which was refused a year ago by the State Board of Charities for financial reasons, was renewed recently, the assurance of $30,000 in cash and pledges having been obtained. The granting of this certificate is opposed by the officials of the Lebanon Hospital, representatives of which appeared before a committee of the board on October 16. The opposition is based on the fact that the proposed new hospital would be within a mile or so of the Lebanon Hospital and on the belief that the establishment of another Hospital in the district is not called for by the conditions. Decision in the matter was reserved.

Obituary Notes.—Dr. George Drury of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1878, and a member of the New York State and Kings County Medical Society, the Brooklyn Pathological Society, and the Alumni Association of the Long Island College Hospital, died at the Skene Sanitarium, Brooklyn, on October 20, aged 56 years.

Dr. Charles A. Ayers died at Philadelphia on October 9 at the age of 62 years. He was graduated from Hahnemann Medical College and Hospital of Philadelphia in the class of 1888.

Dr. William Wright Markoe, a son of the late Dr. Francis H. Markoe of New York, a graduate of the Yale University Medical Department, New Haven, in 1898, and a member of the American Medical Association, died at Charleston, N. H., on October 19, aged 39 years.

Dr. Charles E. Goldsborough of Hunterstown, Pa., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1855, a veteran of the Civil War, and one of the survivors of Libby Prison, died recently at his home, aged 79 years.

Dr. Stewart L. Henry of New Orleans, La., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1866, died at his home, after a protracted illness, on October 11, aged 79 years.

Dr. Arthur Adelbert Downs of Fairfield, Me., a graduate of the Baltimore Medical College, Baltimore, Md., in 1897, a member of the American Medical Association and the Maine State and Somerset County Medical Societies, secretary of the Maine Anti-Tuberculosis Association, and medical director of the Central Maine Sanitarium, Fairfield, died at the Cousins Hospital, Portland, from cerebral meningitis, on October 12, aged 39 years.

Dr. H. C. Thiess of Akron, O., a graduate of the Columbus Medical College in 1880, and a member of the Ohio State and Summit County Medical Societies, died on October 13, from injuries received when the automobile in which he was driving was struck by a trolley car a few hours before.

Dr. John D. Brundage of Westhampton, N. Y., a graduate of the Yale University Medical Department, New Haven, in 1864, and a member of the New York State and Suffolk County Medical Societites and the Associated Physicians of Long Island, died at the home of his daughter in Goshen, Conn., on October 21, aged 79 years.

Correspondence.

REMEDIES FOR SLEEPLESSNESS.

To the Editor of the Medical Record:

Sir:—Your issue of October 18 contains a letter from London in which, among other interesting items, there is a good report of Dr. Cushny's paper on "Remedies for Sleeplessness" and its discussion. Permit me to direct attention to a valuable but unhappily neglected hypnotic that fulfills all the conditions so forcibly stated by Professor Cushny. As I urged in the discussion of his excellent paper, the commendations of drugs pained me, especially since the most highly praised one was an American proprietary medicine that no physician who has respect for his calling would use. When I mentioned this sad fact to Dr. Fortescue Fox, he defended its recommendation by the highest authority in Great Britain on the ground that its composition was known. Why then, I asked, does not this authority prescribe the ingredients instead of using the "registered" name?

I detailed the technique of the wet pack, its physiological action derived from animal experimentation, and the clinical results in the Vanderbilt Clinic, where the students have seen men coming for treatment for long-standing insomnia fall asleep, amid the noise of falling water and other disturbances, and while lying on a hard table. I also detailed the successful result in a desperate case in which suicide had been attempted and six months' treatment in Asheville and the Battle Creek Sanitarium had failed utterly.

In closing the discussion Professor Cushny challenged the right of this remedy, which he claimed as acting by suggestion chiefly, to be admitted, losing sight of the fact that the discussion was on "remedies" and not on "drugs" for sleeplessness. That this is a sad commentary on the benighted condition of British therapeutics I took occasion to point out on the following day in the paper mentioned in your London letter.

S. Baruch, M.D.

51 West Seventieth Street, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE RADIUM INSTITUTE—TUBERCULOSIS AUTHORITY UNDER INSURANCE ACT—CHARING CROSS HOSPITAL—ROYAL DENTAL HOSPITAL—HOSPITAL FACILITIES FOR AMERICANS IN LONDON—SATURDAY FUND—OBITUARY.

London, Oct. 10, 1913.

The Radium Institute invited a select number of Press gentlemen to witness, on October 2, a demonstration of the methods used in handling the substance and to hear an account of the work carried on during the two years since the institute was established by the munificence of Sir Ernest Cassell and Lord Iveagh. In consequence of this meeting the newspapers have published a number of facts, accompanied in some cases by opinions more or less noticeable. Mr. Hayward Pinch, F.R.C.S., medical superintendent, described the work done with water charged with emanation. They would charge the water to a degree many thousand times stronger than could otherwise be obtained, and he reported that water so charged had been found to have the same effects as radium itself. This active water has been largely supplied to medical men in the country, for although it rather rapidly grows weaker it retains its activity long enough for transmission. In three or three and one-half days the strength is reduced to about half. Several cases of arthritis deformans had been greatly benefited.

The Institute claims to possess radium to the value of £80,000, and all this for the purpose of therapeutic investigation. Forty-two applicators are in constant use, varying in strength from 5 to 150 mg., but some patients have been treated with far greater quantities. Sir F. Treves (chairman of committee) said the resources of the institute are at the service of all on the introduction of a medical man. In the last eleven months 400 paying and as many nonpaying patients had been treated, the treatments numbering 3,000 to 4,300, respectively. They tested and weighed radium for medical men and mounted apparatus for them at a nominal charge. They had mounted apparatus for other institutions in Denmark, Germany and the United States. During the International Medical Congress a lantern lecture was delivered to the Dermatological Section, and a number of demonstrations given at the institute. The institute prepares plates and emanation tubes, for which there is a continual demand. This work is under the immediate supervision of Mr. W. L. S. Alton, the director of the institute's chemicophysical laboratory.

The institute is not in debt, a remarkable thing for any medical establishment. But the explanation is the magnificent endowment, apart from which the debt would probably be as great, or greater, than any of the hospitals. Great extension has begun, the rest of the street adjoining the institute has been purchased and further buildings will soon be begun. In them there will be ample provision for investigation and research in all directions and for post-graduate instruction in all that relates to the therapeutical employment of radium.

There is no little confusion as to the tuberculosis scheme of the Insurance Act. It was at first proposed that the London County Council should deal with it and that body resolved to utilize all existing institutions and not to approve any scheme which did not provide for each dispensary to be linked up with a hospital. So the Local Government Board was informed, with the result, apparently, that they determined to intrust the matter to their several local authorities. Accordingly, the Local Government Board has issued a return on the sanatoria approved under the act, in which only two of the teaching general hospitals are stated to have been so approved. The question naturally arises whether tuberculosis should thus be withdrawn from the other clinical hospitals, and in that way have students deprived of the opportunity of studying the disease under the direction of eminent teachers. The hospital authorities, as at present appears, seem to be so much divided that it looks as if they have scarcely realized their position.

At the meeting of the Asylums Board on Saturday last letters were received from ten metropolitan Borough Councils indorsing a resolution of another formerly submitted, that the Asylums Board should become the authority for the residential treatment of the tuberculous, its constitution being enlarged in order for the borough councils to be represented upon it. Letters were received from other bodies on the subject, including one from the local governing board indorsing the one to the County Council, in which they had suggested

it should be the authority through which other agencies should be co-ordinated. The board referred all the documents to the law and parliamentary committee which may perhaps bring an orderly report out of the confusion.

Princess Louise, as president of the Charing Cross Hospital, has made an appeal for a special fund which Lord Lonsdale is raising to free the hospital from its financial liabilities (some £70,000 is needed), and permit the reopening of the five wards which have long been closed. Her Royal Highness' appeal was dated the 3rd inst., and generally published in the press yesterday. In the meantime a statement "went the round" that the committee had decided to reopen the wards for paying patients to accommodate persons just above the usual hospital class but who could pay enough to defray the cost of their maintenance. Two lines of policy are thus simultaneously put forward; it almost looks like divided councils, but this is not the case.

Prince Alexander of Teck presented the prizes at the Royal Dental Hospital on Tuesday, and insisted on the need of high qualifications. He said this was over and over again borne in upon him in his work at the Middlesex Hospital, where he saw how much suffering might be spared the poor if that which could be prevented actually were prevented, and it was the same at this hospital. The care of children's teeth was an example. The donor of a gift to endow a research worker to find the means of preventing dental disease would be a benefactor to the human race.

Americans residing on this side are proposing to endow a ward in the London Hospital, to be devoted exclusively to the use of their compatriots. The suggestion has been favorably received, and perhaps the most distinguished body of patrons of American charitable objects in England has been formed to carry out the idea. Considering the fine American Hospital in Paris it is a little surprising that nothing of this kind has previously been thought of.

Yesterday the Lord Mayor issued the customary appeal on behalf of the Hospital Saturday Fund.

Dr. G. P. Tennant, cousulting physician to the Western Infirmary and to the University Lying-In Hospitals, Glasgow, died on the 13th September, aged sixty-seven. He was a Glasgow graduate, 1867-70, and a Fellow of the Faculty of Physicians and Surgeons. By his will he bequeathed £25,000 to the Glasgow University, for such objects in connection with the Faculty of Medicine as his trustees may select. The residue of the estate he left to the following Glasgow charities: Western Infirmary, the Royal Infirmary, the Victoria Infirmary, and the Royal Hospital for Sick Children.

Dr. Forbes Ross, who died September 18, aged forty-five, was surgeon to the Kensington Hospital, and at one time was a civil surgeon to the Guards' Hospital. He was M.D. Edin., 1893, and later took the F.R.C.S. Eng. He made many contributions to the journals, and was the designer of several instruments and of modifications of others.

Lieut-Col. John Ritchie, R.A.M.C., has died suddenly in his fifty-first year. He graduated at Glasgow, 1884, and joined the Army Service in 1887, served in India, the Gold Coast, and West Africa. He was also in the late South African war. He held the Queen's medal with four clasps, and the Kings with two.

Dr. Inspector-General John Lyon died on September 25. He took M.D., Glosgow, in 1876, entered the Navy in 1871, was at Magdala and Alexandria, and received the Khedive's medal and star. He retired in 1891.

Dr. Carnegie Brown, Honorable Secretary of the Society of Tropical Medicine, died September 30, aged fifty-four. He took M.D., Aberdeen, 1884, and became member of the London College of Physicians in 1906. At one time he had been a Consul in Belgium. He wrote in the Journal of Tropical Medicine on "Myocardial Degeneration in Hot Climates," 1906, and "Malaria in Madagascar," 1907. He also was the author of a monograph on "Sprue," and another on "Amebic Dysentery."

OUR LETTER FROM HAVANA.

(From Our Regular Correspondent.)

TRACHOMA IN CUBA—INFANTILE HYGIENE—THE SAN LÁZARO LEPROSY HOSPITAL—THE THIRD NATIONAL CUBAN MEDICAL CONGRESS.

HAVANA, October 13, 1913.

THE Clinical Society of Havana begun its autumn sessions with the reading by Dr. Horacio Ferrer, a young army surgeon, of an interesting paper on "Trachoma in Pinar del Rio Province," in which he stated that out of nearly 9,000 children examined in the rural districts and in the towns of that province he found about 300 cases of trachoma; the disease being more prevalent the further from Havana was the site examined. Dr. Santos Fernandez, President of the Havana Academy of Sciences, stated that in his opinion Dr. Ferrer's work had been very good but that trachoma prevailed in Cuba to a far greater extent than was believed by Ferrer. Dr. Finlay thought also that trachoma was increasing in Cuba, owing to the bad methods of inspection in places outside of Havana, and to the almost complete absence of expert school inspection. Dr. Francisco M. Fernandez, recently government expert, stated that he had had considerable experience in Pinar del Rio Province. While doing work on trachoma in several towns, he found almost 10 per cent. of the school children affected with the disease.

Dr. Nogueiras of the Hospital Número Uno has taken charge of the Mercedes Hospital during the absence of Dr. Emiliano Núñez, who is in the States on private business.

A new service of Infantile Hygiene has been established in Havana. The city has been divided into eighteen inspection districts, with a doctor in charge of each one. The medical officers have the supervision of all poor pregnant women as well as the inspection of the feeding of all infants of the poor, and suggestions are given to the mothers as to the best way to feed them.

The new Board of Trustees of the San Lázaro Leprosy Hospital begun its duties on the first of this month. Much criticism has been aroused on account of their electing as the president a lawyer, who knows nothing of medicine and much less of leprosy. Incidentally it may be mentioned that it is proposed to change the present site of the hospital to a place in the country bought with the funds of the hospital. The change would be welcome as the present hospital is an eyesore to all who visit the city. The institution has a fund of over a million dollars. Yesterday a cable was received from the sanitary authorities of Porto Rico stating that

the steamer *Manuel Calvo* of the Spanish Transatlantic line had on board a suspected case of bubonic plague. Aerograms sent to the steamer were answered by its captain stating that the case was one of abscess of the thigh and that there was not the slightest danger of it being bubonic plague. The port medical officers have been given instructions as to the strict examination and quarantine of all the passengers when the steamer arrives.

The work of the Executive Committee of the Third Cuban National Medical Congress has been very good, a large number of Cuban physicians, dentists, pharmacists, and veterinary surgeons have been inscribed. The Congress will be held in December, 1914, and the committee hopes to have a large gatherng of Cuban and American medical men in Havana at that time.

4. The Pathological Lesion of Whooping Cough. F. B. Mallory.

1. Relation Between Gynecological and Neurological Diseases.—W. P. Graves points out that the performance of gynecological operations cannot be expected to cure true psychoses, but may greatly improve the mental condition by removing the pelvic irritation of pain and discomfort, while in certain cases, which from the standpoint of the psychiatrist are essentially curable, operations may greatly facilitate or hasten a complete cure. This is a subject of the widest importance and one capable of very great development. The author emphasizes the point that there exists no mysterious or peculiar nerve connection between the female genital organs and the central nervous system, and that disturbances in the former cause manifestations in the latter by the irritation of pain and discomfort. If this simple theory be borne constantly in mind in the practical treatment of patients there will be fewer mistakes on the part of the gynecologist and the neurologist.

2. Pellagra in Massachusetts.—J. B. MacDonald reports two cases of this disease that have been admitted this year to the Danvers State Hospital, Massachusetts. Neither case was recognized prior to admission. One presented on admission a typical picture of typhus pellagrosus, a condition described by Lavinder as "an acute explosion peculiar to pellagra and occurring as an incident in the chronic course of the disease," and by Edward Jenner Woods as "a terminal phase, an acute exacerbation of the usual chronic condition." The other case developed the characteristic skin lesions after a residence of two months, but the history is strongly suggestive of previous attacks of the disease. In the one case the cutaneous lesions had been variously described as eczema, psoriasis, "vagrant's disease," dermatitis, etc., while the existing stomatitis, and gastrointestinal, nervous, and mental disorders obtained different interpretations. In the other, the history received contained nothing suggestive of pellagra. With the appearance of the skin lesions a fuller investigation revealed a long-standing condition of gastrointestinal disturbances coincident with mental depression and confusion. The obscure nervous disturbances said to have existed in this case, the depressive mental state with the added digestive disorders, form not uncommonly the earliest manifestations of the disease. Indeed, instances are not rare in which the mental and gastrointestinal symptoms have existed for years before the skin lesions claimed attention—the so-called pellagra sine pellagra, in which the cutaneous eruptions are so insignificant and of so short a duration as to escape notice or excite no serious consideration from the sufferer or the medical attendant.

1. Syphilis of the Nervous System.—F. X. Dercum emphasizes the importance of making a clear distinction between syphilis of the vessels and membranes on the one hand and tabes and paresis on the other. The facts of the prognosis of the parasyphilitic affections make such a distinction imperative. It has become necessary to go one step further and to emphasize the distinction between the two great parasyphilitic affections themselves. The clinical distinction between tabes and paresis has of course long been admitted. It is the occurrence of taboparesis, that is, the form in which spinal symptoms appear early, which has tended to obscure the subject. The knee jerks may in such cases be much diminished or even lost. If at the same time incoordination is noticeably absent, the picture of locomotor ataxia may be more or less closely simulated. However, certain striking differences obtain between taboparesis and tabes. In the first place, the history of tabes is one of very slow and gradual evolution. There is a history of difficulty of walking in the dark, of unsteadiness in the mornings while washing the face, of shooting pains more or less severe, of gastric crises, of delayed sensation in the feet and legs, of disturbances of micturition. Early, too, the ataxia becomes a marked feature. Finally, pupillary disturbances make their appearance. These differ notably from those met with in paresis. Most frequently they consist of a narrowing of the pupils with an early impairment or loss of the light reaction. It is to be especially noted, however, that in tabes the pupils are equal; inequality is excessively rare. Secondly, the impairment of the light reaction is commonly the same on the two sides; sluggishness and the degree of loss are usually not more pronounced on one side than on the other. In taboparesis, the evolution of the symptoms may be slow, though as a rule it is far more rapid than in tabes. Secondly, mental symptoms make their appearance relatively soon, so that the real nature of the case early becomes apparent. Again, incoordination though present is rarely so pronounced as to play a striking rôle in the early period.

2. Salvarsan and Syphilis.—A. L. Wolbarst reports a series of seven cases of syphilis in which the patients received but one intramuscular injection of salvarsan; no other treatment was administered; they all became, and remained, perfectly well; there have been no recurrences of any kind, and all have gained remarkably in body weight. The periods since the administration of the injection vary from two years and ten months to two years and one month, an average of two years and six months; in four of these cases the Wassermann reaction has been taken repeatedly and has persistently remained negative; it therefore appears that one intramuscular injection of salvarsan has removed all manifestations of the disease and has produced a persistently negative Wassermann reaction. No other method of treatment has ever produced results equally satisfactory.

5. Pyelitis.—By C. J. Bartlett. (See MEDICAL RECORD, July 19, 1913, page 131.)

7. Paresis in the Negro.—F. M. Barnes, Jr., states that paresis is more frequent among the colored race as a whole than among the white, and nearly three times as frequent in the colored female as in the white. Fifty per cent. of the author's cases were admitted between the ages of thirty and forty years. In about 50 per cent. the duration of the disease on admission was eight months or less, the balance having been in existence for a longer period, bringing the general average duration prior to the beginning of hospital treatment up to about one year plus, the period usually given for whites. In fifty-eight per cent. of the cases the onset was gradual and in sixty-two per cent. the usual gradually progressive course was followed. Definite remissions in the course of the disease occurred in thirteen per cent. of the cases. Hereditary taint, such as alcoholism, nervous or mental diseases, syphilis, tuberculosis, etc., was noted in about twenty per cent., but in only one instance, a case of juvenile paresis, was it possible to prove a similar heredity. Fifty per cent. of the patients were alcoholic, but only one excessively so, and it is believed that the alcohol in these cases is more symptomatic than causal. Head trauma was noted in only six instances, and in none could a definite connection between it and the paresis be established. Previous attacks of mental disorder in colored paretics are rare, having occurred in this series in but four patients, and in no instance was the attack similar to the symptoms manifested by the patient as a paretic.
